Systemic Action.—The effects of strychnine upon all the bodily systems are to be understood by regarding it as a direct and pure stimulant, its action upon the motor centres of the cord, and to a lesser extent upon those of the brain, vastly predominating. Thus it stimulates the circulation (the vagal effect having been considered above), both through the heart and through the vasomotor system, promptly and strongly increasing blood pressure; it powerfully stimulates the respiration, increasing both the rate and the strength of the respiration; it increases metabolism and waste and raises the temperature moderately; it increases the activity of all muscular tissue, both voluntary and involuntary, partly, as already stated, by direct action, increasing excitability, but to a far greater extent through stimulation of the motor centres. Thus, slighter stimuli are required to set the movements going, and the movements themselves exhibit increased strength. All the special senses are sharpened, especially that of sight, and this more particularly for blue colors. All of these effects will be more thoroughly understood by consulting our account of strychnine poisoning under the head of *Nux Vomica*, which account will serve also to explain the reverse symptoms, occurring as after-effects in that condition.

Therapeutical Uses.—The very numerous therapeutical uses for strychnine may, for the most part, be inferred from what has preceded. It can be employed to stimulate almost any of the lagging vital powers. It is so employed, most largely perhaps, in promoting the functions in the aged. It is also very valuable in the stimulation of those persons whose habits of life are unnatural, in that they do not take sufficient exercise or perform other ordinary hygienic duties. If careful attention be given to the patient, the most valuable effects can be secured from strychnine by utilizing its action as an aid in inducing the indolent to take needed exercise while under its influence. While it cannot be relied upon for overcoming a condition of chronic constipation, it becomes, in connection with other drugs, a most valuable aid in this direction. Its uterine stimulation cannot be overlooked, either from the standpoint of undesirable effects or from that of desirable effects. It is a pronounced aphrodisiac. In rendering cardiac support in such exhausting diseases as pneumonia, it is of the utmost value. Its value as a tonic in all ordinary forms of impaired digestion has been indicated above.

Although these beneficial effects from the use of strychnine are almost marvellous, it is to be remembered that, since its action is purely stimulating, it can easily be so used as to result in the most damaging way. It must never be relied upon to take the place of natural powers and conditions, but should always be considered as a means of inducing their activity. Otherwise the system can easily become exhausted, a condition of depression made to follow that of stimulation, it being then found extremely difficult to discover any other means for again stimulating them.

COMPOUNDS, PREPARATIONS, AND DOSES.—Strychnine, because of its high insolubility, is rarely used except in the form of its salts, of which the sulphate is official. It occurs in intensely bitter, white, prismatic crystals, which effloresce in the atmosphere. It is soluble in fifty parts of water, and in one hundred and nine parts of alcohol, but is nearly insoluble in ether. The dose of strychnine itself is 0.001 to 0.006 gm. (gr. $\frac{1}{60}$ to $\frac{1}{10}$). Strychnine is combined in many popular formulæ with the hypophosphites, and with iron, quinine, and other tonics. Two such are official: the Citrate of Iron and Quinine (Ferri et Strychninæ Citras), containing one per cent. each of strychnine and citric acid, with ninety-eight per cent. of iron and ammonium citrate, the dose 0.06 to 0.2 gm. (gr. i. to iij.); and the Syrup of the Phosphates of Iron, Quinine, and Strychnine (Syrupus Ferri, Quininæ et Strychninæ Phosphatum), containing 0.02 per cent. of strychnine, two per cent. of soluble ferric phosphate, three per cent. of quinine sulphate, 4.8 per cent. of phosphoric acid, ten per cent. of glycerin, and five per cent. of water, in syrup, the dose 2 to 4 c.c. (fl. ʒ ss.–i.).

Henry H. Rusby.

STRYCHNIN AND NUX VOMICA, POISONING BY.—The poisonous quality of nux vomica was referred to by Wepfer and by Valentine in the latter part of the seventeenth century. Strychnin was discovered by Pelletier and Caventou in 1818. Blumhardt, in 1837, was probably the first to report the death of a human being by this poison. Although Wainwright probably used strychnin as an instrument of murder in 1831, the first homicidal case which was the subject of a trial of which we find record occurred in Canada in 1851.

A collation of 529 cases of strychnin poisoning shows a relatively high proportion of homicidal and suicidal poisonings. Of the whole number, 264, or 49.9 per cent., were suicidal; 100, or 18.9 per cent., homicidal; and 150, or 28.3 per cent., accidental. Poisonings by strychnin are of more frequent occurrence in Great Britain than in the United States, owing to the fact that rat poisons used in the former usually contain strychnin, while those used in this country contain arsenic or phosphorus.

SYMPTOMS.—The symptoms of poisoning by strychnin or nux vomica are very characteristic.

If the dose be relatively small, although capable of causing death, there is frequently at first an initiatory stage of nervous exaltation without any violent symptoms, whose duration varies inversely with the magnitude of the dose and the rapidity of absorption. The special senses are much more acute than normally, the mental functions are active, the patient is restless, and experiences a sensation of itching. But with large doses the onset is usually very sudden.

Soon twitchings of individual groups of muscles occur, followed by violent tetanic convulsions. During the spasms there is, in the great majority of cases, marked opisthotonos. The head is thrown sharply back, the body bent backward, the abdominal and thoracic muscles firmly contracted, the lower extremities rigid, and the soles of the feet bent inward and strongly arched. The lower jaw is fixed, the eyeballs are protruded, the pupils dilated, the expression of the countenance is distorted, the lips are cyanotic, the mouth is marked with froth—frequently bloody from the tongue being caught between the closing teeth—and the neck is swollen. In some exceptional cases emprosthotonos or pleurothotonos is observed instead of opisthotonos.

The spasm gradually passes off, the muscles relax, the eyes and pupils become normal, and respiration is resumed. The patient speaks, usually calls for air, desires to be held, and is in dread of impending death. Indeed, consciousness and intellectual activity do not seem to be impaired during the spasms.

After the first convulsion others, similar in character, occur, either spontaneously or in consequence of very slight unexpected excitation. An attempt to move the patient, a slight jarring of the floor or bed, a sudden noise, a slight draught of air, or even a flash of light, is sufficient to provoke a spasm if the patient do not expect it. On the other hand, much more active excitation fails to call forth a spasm if the patient be not taken unawares; and he frequently asks to be rubbed, held down, or moved. When the spasm recurs spontaneously, the patient usually announces its coming some seconds in advance, and asks to be held.

The number of convulsions usually varies from three to ten, but in prolonged cases, whether fatal or non-fatal, the number may be much greater. Their duration is from thirty seconds to five or even fifteen minutes. The intervals vary in duration from forty-five seconds to one hour, or even to one hour and a half; usually they last for from five to fifteen minutes.

In cases terminating in recovery the interval between the spasms increases in length and the convulsions become less active and shorter in duration, and finally cease, leaving the patient in a condition of great muscular fatigue, and with increased reflex irritability. In fatal cases death results from one of two causes: In some cases death is due to asphyxia by fixation of the muscles of respiration during a protracted spasm; in others it is due to exhaustion, and occurs during the non-tetanic period. In most fatal cases death occurs during or after the fourth or fifth tetanic seizure, although cases have occurred in which the patient has succumbed at a later period, and others in which life was extinguished during the third, second, or first convulsion.

Duration.—The rapidity of action of strychnin is modified by the form in which it is taken, whether in solution or in a hard and difficultly soluble pill, and by the length of time which is allowed to elapse before treatment is resorted to.

In 78 cases, in which the time of first appearance of the symptoms was noted, the period was "directly, or very soon," in 20; from three to thirty minutes in 40; from thirty minutes to one hour in 7; from one to two hours in 6; and from two to three hours in 5. The average period of delay is, therefore, within twenty minutes. The extremes are "directly" and three hours. The appearance of strychnin symptoms is delayed when large doses of opiates are taken with it.

The total duration of strychnin poisoning is also short, whether it terminate in death or in recovery. Of 143 fatal cases of which the duration is stated, 77 died within one hour; 32 in from one to two hours; 10 in from two to three hours; and 24 in from three to eighteen hours. In the majority of these cases the entire duration was less than one hour. The extremes were "immediately" (from a dose of one and three-fourths grain, combined with an equal quantity of nux vomica), and eighteen hours (from a dose of three grains), both adult males.

In non-fatal cases recovery is usually rapid, the active symptoms cease within a few hours, and, after cessation of the spasms, the patient may be considered as out of danger, although in exceptional cases great muscular prostration and occasional involuntary muscular contractions continue for some days.

Differential Diagnosis.—The disease bearing the closest resemblance to strychnin poisoning is traumatic tetanus. In poisoning by strychnin the attack is more sudden than in tetanus, and the entire history of the case is compassed within a few hours, in place of lasting for days. The spasms follow each other at shorter intervals, and are of shorter duration, in strychnin poisoning than in tetanus. In the latter, trismus is one of the earliest and most prominent of the characters, while in the former it occurs later, if any succession of symptoms be observable, and may be insignificant as compared with the violent tetanic contraction of the respiratory muscles. During the intervals between the convulsions due to strychnin the muscles are usually relaxed, while in tetanus they remain more or less rigid, particularly those of the lower jaw. The chief points of distinction are in the much more rapid progress of strychnin poisoning, and, in the great majority of cases, in the history of the onset, which, in the poisoning, follows, with very little warning, within two hours or less, the ingestion of some bitter substance, but in tetanus is gradually developed several hours or days after an injury.

Uncertainty concerning the diagnosis between epilepsy and strychnin poisoning can only occur in the very exceptional case of an unknown person dying during a single convulsion. In such an event chemical analysis would decide the question definitely. In other cases the history of the case, the much longer interval between the paroxysms in epilepsy, and the more distinctly tonic character of the spasms in strychnin poisoning, are sufficient to establish the distinction.

In cases of poisoning of pregnant women by strychnin (two such are cited by Wharton and Stillé, pp. 443, 625) the distinctions between the effects of the poison and puerperal convulsions are of importance. The principal diagnostic point is in the fact that in puerperal convulsions the patient is entirely unconscious of what occurs, either during or between the convulsions, while in strychnin poisoning consciousness remains unimpaired, except immediately before death. The detection or non-detection of strychnin in the body would remove all doubts.

Lethal Dose.—The smallest amount of strychnin which has been known to cause the death of an adult is 0.016 gm. (= gr. $\frac{1}{4}$), which produced violent symptoms in ten minutes in a female, aged thirty-six, and death in one hour and forty-five minutes (*Medical Times and Gazette*, 1854, p. 376). Double this quantity, 0.032 gm. (=gr. ss.), caused death in two cases. In one of these (case of Dr. Warner) a physician took by mistake half a grain of the sulfate, was violently convulsed in five minutes, and died in twenty minutes. Less quantities have produced dangerous poisoning in adults. Christison cites the case of a child of three years which was killed in four hours by 0.004 gm. (= gr. $\frac{1}{16}$).

On the other hand, numerous cases are on record in which much larger doses have been taken without causing death. Thus Campbell (*Lancet*, 1856, ii., 695) relates a case in which a man, aged thirty, took 0.65 gm. (= gr. x.) of strychnin and recovered. Shaw (*American Journal of the Medical Sciences*, 1856, 547) cites the case of an adult female who recovered from the effects of a dose of 0.65 to 0.97 gm. (= gr. x. to xv.). Tschepke (*Deut. Klin.*, 1861, ex "Maschka Handb.," ii., 613) gives a case of a pharmacist who took from 0.48 to 0.72 gm. (= gr. viiss. to xi.) of strychnium nitrate dissolved in about 30 gm.)= fl. ℥ i.) of bitter-almond water, and, after half an hour, having experienced no symptoms, 0.6 gm. = gr. ix.$\frac{1}{4}$) of morphium acetate, also dissolved in bitter-almond water. Subsequently, being still capable of locomotion, he poured chloroform upon his pillow and lay with his face upon it. An hour and a quarter after taking the first dose he suffered violent symptoms of strychnin poisoning, from which he, however, recovered under treatment by emetics and tannin. Wilson (*American Journal of the Medical Sciences*, 1864, N. S., xlviii., 70) cites a case in which the amount taken was 2.6 gm. (= gr. xl.), probably the largest not causing death.

Treatment.—The ends to be aimed at are the removal of any unabsorbed poison from the stomach, if possible, and the prevention or mitigation of the paroxysms. Chloral should be generously administered, followed by inhalations of chloroform sufficient, and sufficiently prolonged, to control the convulsions until the poison shall have been eliminated, as it is with considerable rapidity. In the exceptional cases in which the patient is seen before the tetanizing action of the poison has been established, the stomach should be washed out as expeditiously as possible with a strong infusion of tea, or a solution of tannin in some form, or water holding powdered charcoal in suspension. Usually stomach lavage must be deferred until the patient has been brought, at least partially, under the influence of the anæsthetic. No reliance is to be placed upon camphor, albumen, opium, aconite, cannabis indica, or tobacco, which have been suggested as so-called physiological antidotes.

Post-mortem Appearances.—There are no peculiarities discoverable, on external or internal examination, which are characteristic of this form of poisoning. Rigor mortis is more rapidly established and continues for a longer period in most cases. According to Wharton and Stillé, rigor mortis was very marked in the body of a woman exhumed two weeks after death (*Medical Jurisprudence*, ii., 445). Taylor ("Poisons," third American edition, 676) states that cadaveric rigidity was well marked in the body of Cook two months after death. Usually the body is relaxed at death and soon stiffens, but in some cases the tetanic spasm merges into rigor mortis. But instances are met with in which cadaveric rigidity has disappeared in from twenty-four to forty-eight hours. In some cases the hands are firmly clenched and the soles arched after the other muscles have become relaxed. Rigidity is of shorter duration in the bodies of those in whom the spasms have been more or less controlled by treatment during life, than in those who have died without medical interference. The surface is usually livid, but not in all cases. Sometimes lividity is confined to the fingers, and in some cases the inner surfaces of the thighs and arms assume a red color.

The internal appearances are still less characteristic. The blood is usually fluid and dark. The vessels of the scalp, the brain and its coverings, and of the spinal cord, as well as the lungs, are in most cases congested. The heart is usually empty and sometimes firmly contracted, the right side being less so than the left, and sometimes distended with dark, fluid blood. The bladder is usually empty, though in some cases it has been found to be nearly full of urine. Occasionally ecchymotic spots or patches of congestion are observed in the stomach.

Analysis.—In cases in which the analysis is not to be limited to a search for strychnin, the systematic method of Dragendorff for the separation of alkaloids and glucosids from organic mixtures should be followed. By this method any strychnin which may be present in the substances examined will be found in the residues of evaporation of the benzene extract from the alkaline aqueous solution.

In all cases it is advisable to resort to Dragendorff's method, even when the history of the case points very directly to strychnin, as any question subsequently arising as to the presence or absence of another alkaloidal or glucosidal poison can then be determined.

In some exceptional chemico-legal cases, and when the physician wishes to determine the presence or absence of strychnin in the urine during the life of the patient, an abridged modification may be used. If the substances to be examined be solid, they should be finely divided and placed in a flask, to which water, rendered distinctly acid with sulfuric acid, is added in sufficient quantity to cover the solid. After agitation, the reaction of the liquid is to be determined, and, if not distinctly acid, it is to be rendered so by the addition of dilute sulfuric acid. The flask and its contents are then to be heated to 40°–50° C. for six or eight hours, after which the liquid is to be filtered off. The extraction should be repeated four or five times with water. The united acid filtrates, which contain any strychnin that may be present in the form of the sulfate, are then evaporated to the consistence of a thin syrup over the water-bath. The residue is mixed with four volumes of strong alcohol, gradually added during stirring, and allowed to macerate twenty-four hours. The cold alcoholic liquid is filtered off, the residue on the filter washed with strong alcohol, and the filtrates and washings evaporated over the water-bath until free of alcohol. The residue, thinned with water if necessary, is transferred to a stoppered cylinder. The solution should not exceed 50 c.c. in bulk, and may be less. About 50 c.c. of benzene (boiling-point not over 85° C.) are then added and the cylinder strongly agitated once every five minutes for about half an hour. The benzene layer is then removed by the separatory funnel and a fresh portion added to the aqueous liquid, which has been returned to the cylinder. This extraction of the acid aqueous liquid is repeated (usually four or five times) until the benzene no longer leaves a residue on evaporation. The purpose of this extraction is to remove pigmentary and other substances, whose presence materially interferes with the reactions. The aqueous liquid is now rendered distinctly alkaline with ammonium hydroxid, and again repeatedly extracted with benzene as described above, but the benzene layers now separated are evaporated in several watch-glasses, and it is to the residues so obtained that the tests for strychnin are to be applied.

If the substance to be examined be a liquid, it should either be evaporated to dryness, the residue extracted with acidulated water, and the filtered aqueous extract treated with benzene, the watery solution being first acid, then alkaline, as above described; or, in the case of a simple aqueous solution, the treatment with benzene may be applied directly, care being had as to the reaction.

In order that the tests may be relied upon, particularly when the alkaloid is present in small amount, as in the case of absorbed strychnin, it is essential that foreign substances be removed as completely as possible. Therefore, if the benzene residue from the alkaline solution be colored, it should be purified by dissolving it in a small quantity of dilute sulfuric acid, agitating with benzene, rendering alkaline, and again extracting with benzene.

Tests.—1. Strychnin crystallizes from an alcoholic solution in small, four-sided, orthorhombic prisms, terminating in four-sided pyramids; sometimes also in small hexagonal plates. Precipitated by ammonia from solutions of its salts, it forms slender, needle-like, four-sided prisms.

2. The taste of strychnin is intensely and persistently bitter, with a faintly metallic after-taste. The bitter taste is still perceptible in a solution containing only one part of strychnin in two hundred thousand of water.

3. Strychnin dissolves in concentrated sulfuric acid, forming a colorless solution of the sulfate. If, now, nascent oxygen be generated in the solution, a peculiar play of colors is produced; at first, and but for an instant, blue (this is sometimes absent), then violet, which gradually changes to red, and then to yellow.

This test, which is most delicate and characteristic, may be applied in a variety of ways.

The sulfuric-acid solution may be placed upon a strip of platinum foil connected with the positive (platinum) pole of a single Grove cell, and a platinum wire, connected with the negative (zinc) pole, brought into contact with the upper surface of the drop of liquid. The nascent oxygen liberated at the foil produces a purple-violet blotch.

The sulfuric-acid solution may be placed in a watch-glass upon a white background, and a minute fragment of some solid substance capable of yielding oxygen by contact with sulfuric acid drawn through it with a stirring rod. The path of the solid is marked by a streak of color passing through the shades above mentioned. Either manganese dioxid, cerium oxid, potassium permanganate, dichromate or ferricyanid, or lead peroxid may be used. Manganese dioxid, potassium permanganate, and cerium oxid are preferable to the other substances mentioned, and each should be used with separate portions of the residue, if there be sufficient. The dichromate acts quite rapidly, the blue color is not produced, and in solutions containing no strychnin only a yellow color is communicated to the liquid. The manganese dioxid acts much more slowly by reason of its less solubility, the blue color is developed, and, in the absence of strychnin, the liquid remains colorless. If the reaction is obtained as above described another portion of the residue is moistened with concentrated sulfuric acid and heated in an air oven at 130° C. for five minutes, cooled, and treated with the dichromate or peroxid. Strychnin is not affected by the acid at this temperature, but other substances giving color reactions not unlike those belonging to strychnin are either colored by the acid alone or are destroyed. If the material be too highly darkened or blackened when heated with the acid, the cooled liquid should be rendered faintly alkaline, extracted with chloroform, and the residue tested for strychnin. (See Witthaus and Becker, *Med. Jur.*, iv., 808.)

The reaction is interfered with to a greater or less degree by the presence of sugar, morphin, or other reducing agents, brucin, and other substances; therefore the foreign bodies should be removed as completely as possible before the test is applied.

This color reaction is distinct with gr. $\frac{1}{60000}$ of strychnin.

4. The physiological test, first suggested by Marshall Hall, is also extremely delicate. A small frog is held by the hind legs, the skin of the back over the coccyx is raised by a pair of forceps, and a small incision made through the skin into the lymph pouch with a pair of pointed scissors. A few drops of the solution under examination are then allowed to flow from a pipette into the lymph pouch, and the animal is placed under a glass shade. If the liquid contain strychnin, the animal becomes uneasy in about ten minutes; the respiration is accelerated; and violent tetanic convulsions are provoked by striking upon the table, by blowing upon the animal, or by other slight irritations.

5. A solution of iodic acid in concentrated sulfuric acid colors strychnin brick-red, the color changing to violet.

6. Solution of potassium dichromate causes a yellow, crystalline precipitate in solutions of strychnin or of its salts. If this precipitate be moistened with sulfuric acid, the play of colors described in 3 is produced.

Other reactions of strychnin are the following: With solutions of the alkalies, or alkaline carbonates, a crystalline precipitate of strychnin from moderately concentrated solutions of its salts. With tincture of iodin, or a solution of iodin in potassium iodid solution, a dark red-brown precipitate. With platinic chlorid and with auric chlorid, light-yellow precipitates, gradually becoming crystalline. With potassium-iridium chlorid, a dark brown precipitate, which disappears on agitation, but gradually reappears in the form of crystals. With potassium platinocyanid, a white, crystalline precipitate. With potassium-cadmium iodid, a white, flocculent precipitate. With potassium iodhydrargyrate, a fine, white precipitate. With phosphomolybdic acid, a yellowish-white precipitate. With picric acid, a yellow precipitate, which gradually becomes crystalline. With tannic acid, an abundant, white precipitate.

Failure of Detection.—The reactions of strychnin are clearly defined, and it is difficult to suppose a case of death from the effects of this poison in which a properly conducted analysis would not reveal the presence of the alkaloid in the cadaver. It is unquestionable that death may result from the action of certain corrosives and poisons, without any trace of the substance remaining in the body after death. In cases in which a mineral acid or alkali destroys life by starvation, weeks or months after the corrosive has been taken, and in cases of death from digitalis, on the fifth or sixth day, the agent which was the remote cause of death has been eliminated before the fatal termination, and consequently will not be detectable by analysis. The duration of a fatal case of strychnin-poisoning is, however, so short (the maximum lapse of time being six and a half hours, and the average less than one hour from the taking of the poison) that it is, to say the least, highly improbable that a person should die from the effects of this poison and no trace of it remain in the body.

Yet cases have occurred in which death has been undoubtedly due to strychnin, and an analysis has nevertheless failed to reveal the presence of the alkaloid in the cadaver. An historical instance is the case of Palmer, tried in London in 1856, in which Professor Taylor, who made the analysis, did not obtain chemical evidence of the presence of strychnin, although the deceased, Cook, was seized with violent tetanic convulsions fifty-five minutes after taking the poison, and died in about fifteen minutes thereafter. The failure of this analysis (for such it must be considered, as complete elimination in so short a time is not possible) was the subject of much bitter controversy, and seems to have permanently warped the mind of Dr. Taylor on the subject of chemico legal evidence. It was due to two causes, both avoidable. The autopsy was conducted without the commonest precautions necessary in such cases. The defendant was present, and accidentally (?) caused the loss of the contents of the stomach; and the solid viscera were only obtained for analysis at a later date. But the loss of the contents of the stomach, although they probably contained strychnin in larger quantity than the tissues, would not have caused complete failure of the analysis had the analytical processes been properly conducted.

When the amount of strychnin present is large, positive reactions may be obtained even in the unpurified residues; but when the amount is small, as it must necessarily be when absorbed, it is imperative that the alkaloid be freed from other substances as completely as possible before the tests are applied.

Influence of Putrefaction.—Strychnin is one of the most stable of the alkaloids, and remains unaltered in contact with putrefying animal substances for a long time. Cloetta obtained distinct reactions from viscera containing strychnin which had been buried three, six, and eleven and a half months (*Arch. f. path. Anat.*, Bd. xxv., p. 369). Rieckher (*Zeitsch. f. anal. Chem.*, vii., 400) demonstrated the presence of strychnin in a mass of heart, lung, and liver exposed to the ordinary variations of temperature, with which it had been mixed eleven years previously. (See *Ptomains*, Vol. VI., p. 792).

Rudolph A. Witthaus.

STRYKER MINERAL SPRINGS.—Williams County, Ohio.

Post-Office.—Stryker. Visitors received in private families.

The village of Stryker is located on the Air Line division of the Lake Shore and Michigan Southern Railroad. The springs are pleasantly located in the village. They have been allowed to languish somewhat, but we are informed that they have recently passed into the hands of Dr. C. F. Mignin, who proposes to repair and refit the bath-houses, with the intention of establishing a first-class sanitarium. The following analysis of the water was made in 1870 by S. H. Douglas, analytical chemist:

One United States gallon contains (solids): Calcium bicarbonate, gr. 68.30; iron bicarbonate, gr. 9.93; potassium sulphate, gr. 185.34; sodium chloride, gr. 231.86; magnesium chloride, gr. 118.96; silica, gr. 2.63; hydrosulphuric acid, gr. 4.49; total, 621.51 grains.

This water is very rich in valuable chemical compounds. It possesses an exceptionally large quantity of potassium sulphate, which with chloride of magnesium gives it efficient laxative and cathartic properties. The water is also a rich chalybeate, and should be valuable in anaemic and debilitated states, especially when attended by sluggishness of the liver and constipation. *James K. Crook.*

STYPTICIN, cotarnine hydrochloride ($C_{12}H_{13}NO_3.HCl.H_2O$), obtained by the oxidation of narcotine, an opium alkaloid, occurs in bitter yellow crystals which are soluble in water and alcohol. The solutions slowly darken on exposure to light. Chemically it differs but slightly from hydrastinine hydrochloride ($C_{11}H_{11}NO_2.HCl.H_2O$); and clinically it exerts a similar action on uterine hemorrhage.

Falk, of the Pharmacological Institute of Berlin, states that it paralyzes the motor cells of the spinal cord, is mildly narcotic, and stimulates peristalsis. It has no direct effect upon the circulation and is depressing to respiration, death being due to respiratory paralysis.

Rousse and Walton, Marfori, and others, however, assert that it stimulates the heart, and that it controls hemorrhage by vaso-constriction. It does not coagulate the blood. As to its effect on uterine contraction there are conflicting statements, MacNaughton Jones and a few other writers believing it contraindicated in pregnancy, while d'Alessandro, Beadles, and many other obstetricians, have found it most useful in threatened abortion.

The only use of stypticin is to control hemorrhage, and the conditions in which it is especially indicated are: menorrhagia, puerperal hemorrhage, subinvolution, climacteric hemorrhage and hemorrhage dependent upon peri-uterine or adnexial disease. Boldt recommends it highly in the profuse and irregular menstruation of virgins in whom there is no detectable pathological lesion. In hypertrophic endometritis and uterine fibroid it seems to act successfully in only a limited number of cases, though in the latter condition H. D. Ingraham found it better than ergot, hydrastis or thyroid, and MacNaughton-Jones writes: "The hemorrhages in which it proves of most service are those due to uterine interstitial fibroid," . . . etc. The drug has been given with apparent good result in hæmoptysis, hæmatemesis, hæmaturia, and the menstrual neuroses.

The dose is 0.02–0.06 gm. (gr. $\frac{1}{3}$–i.) several times a day in pearl, capsule, or solution. In menorrhagia the larger dose is given for two or three days before the expected menstruation. The only ill effects noted by Goldschmidt from a dose of 0.03–0.06 gm. (gr. ss.–i) every two or three hours for a week, were nausea, and heaviness and constriction in the stomach. Where a prompt effect is desired 2 c.c. (♏xxx) of the ten-per-cent. solution may be administered hypodermatically in the gluteal region. The injection is non-irritating (d'Alessandro).

Locally stypticin has been applied to the cavity of the uterus and to bleeding tooth cavities; and it is used in rectal hemorrhage, nosebleed, and following small operations. A very useful form for local employment is the stypticin-gauze or stypticin-cotton, made by soaking the gauze or cotton in a ten-to-fifty-per-cent. solution of stypticin and allowing it to dry. *W. A. Bastedo.*

STYPTICS. See *Hæmostatics.*

STYRON, phenyl-allyl alcohol, ($C_6H_5CH:CH.CH_2.OH$), is a thick brown oily fluid, used as an antiseptic and deodorizer. *W. A. Bastedo.*

SUBARACHNOID COCAINE INJECTIONS. See *Spinal Cocainization and Lumbar Puncture.*

SUBLAMINE, ethylene diamine mercury sulphate, is a red, very soluble salt of mercury, which is employed as a non-irritant antiseptic substitute for corrosive sublimate. It is not decomposed by soap, does not readily coagulate albumen, and does not harden the skin; yet many experiments have shown it to possess marked bactericidal properties, with a greater penetrating power than has mercuric bichloride. Being non-irritating, it may be used in concentrated solution. Bischof, Swinburne, Dunlap, Reineke, and many others have spoken highly of its advantages in general surgery. Moir has employed it as a vaginal douche. It is ordinarily used in the same strength as the bichloride.

The ethylene diamine mercury citrate has practically the same properties, but is a liquid. It is used by Zweifel in his obstetric wards, and by Kronig and by Blumberg in gynecology. *W. A. Bastedo.*

SUCCUS ENTERICUS.—This fluid is the secretion of the minute glands present in the wall of the small intestine, and it is probably furnished chiefly by the cells of the glands of Lieberkühn. It was first obtained in a pure condition by Thiry, who employed for this purpose an artificial tube of intestine prepared by cutting across the small intestine at two points about 20 to 30 cm. apart, without interfering with the mesentery, restoring the continuity of the intestine by stitching the upper border of the upper incision to the lower border of the lower incision, and then, after closing the lower end of the isolated portion of gut, attaching the upper end of it to the abdominal wound. In this way a living test tube of intestine is obtained, in which the effects of stimulation upon the secretion can also be studied. This procedure was later modified by Vella, who left both ends of the isolated piece of gut open and attached to the abdominal incision. A fistula obtained by the latter method is commonly called a Thiry-Vella fistula, and is the form now usually employed in experimental work.

Opportunity has also been taken by clinicians of studying the succus entericus in man, in cases in which accidental isolation of loops of gut has occurred.

A different method of observation was introduced by Hermann, who closed both ends of the isolated loop so as to form a ring and then restored it to the abdomen and examined it after several days had elapsed. Voit has also used a similar method, merely suturing the two ends of the loop up and then replacing in the abdomen. In both modes of experiment the continuity of the shortened gut is of course restored, as in making a Thiry-Vella fistula.

Such isolated loops left in the intestine for some days are found to be filled with a solid core of a yellowish-gray color, consisting of inspissated succus entericus and débris of intestinal cells; it also yields a large amount of ethereal extractives which probably are produced in the degenerative changes of the intestinal mucous membrane.

The succus entericus secreted into a Thiry-Vella fistula has frequently been described; it is a limpid, opalescent, light-yellow-colored fluid, of strongly alkaline reaction, and effervesces on the addition of acids. It contains coagulable proteid and mucin. It is yielded more abundantly by the lower part of the small intestine than by the upper, and it is stated that the more copious secretion of the lower end contains less mucin.

Human succus entericus has been investigated by Tubby and Manning, who obtained an average daily yield of 27 c.c. during a period of some months from a length of three and one-half inches of gut situated eight inches above the ileo-cæcal valve. This fluid was opalescent, brown in color, and strongly alkaline to litmus. It contained proteid, and did not reduce Fehling's solution, or give any color tests with iodine. The presence of lactates was shown by increase in color of very dilute ferric chloride solution and by a positive effect with Uffelmann's reagent.

It inverted both cane sugar and maltose, and had a certain amount of diastatic action upon starch. The inverting ferment present in the juice adhered mechanically to the mucin, which was often thrown out of solution.

All authors are agreed as to the presence of an inverting enzyme for disaccharides, but some deny a diastatic action on starch, and there is little doubt that the action here is much feebler than that of the absorbing intestinal cells. Thus Röhmann found that starch disappears from a Thiry-Vella fistula much more rapidly than could be accounted for by the feeble action of the succus entericus, and Brown and Heron state that the dried mucous membrane hydrolyzes starch much more rapidly than do clear watery infusions of the mucous membrane.

The conditions of secretion appear to vary in different animals; thus in the sheep, according to Pregl, secretion occurs continually, although it is augmented in the first two or three hours after a meal, while in dogs in which fistulæ have been established little secretion occurs except when the intestine is stimulated. The taking of food acts as a reflex stimulus, as do also mechanical or electrical stimuli when applied directly to the mucous membrane. The introduction of such substances as starch, sugar, or peptone also evokes a secretion. Certain drugs, such as pilocarpine, also cause a secretion.

If all the nervous connections of a loop of gut are severed, it has been shown that this becomes distended by secretion; but if the inferior ganglia of the solar plexus and their connections on the superior mesenteric artery are left in connection with the gut this paralytic secretion does not take place.

It has recently been shown that the succus entericus contains, in addition to the digestive enzymes above mentioned, others of a peculiar and interesting type.

Thus Cohnheim has shown that it contains an enzyme which he has named *erepsin*, which possesses the power of converting albumoses and peptones into amido-acids which no longer give the biuret reaction. The presence of this enzyme would appear to furnish a safeguard against the loading up of the organism by excess of digested proteids which could not be dealt with by the absorbing cells.

A still more interesting enzyme is that named *enterokinase* by its discoverer Pawlow.

It would appear from these researches that the greater part of the proteolytic enzyme of the pancreatic juice is discharged into the intestine in the inert form of trypsinogen, and that this enzyme, enterokinase, which is present in the succus entericus, possesses the power of converting the trypsinogen into trypsin.

The experimental basis for this view is that pancreatic juice alone is almost inert with regard to proteids, so also is succus entericus; but if the two fluids be mixed, an energetic action at once commences. This power of conferring activity upon the pancreatic juice is lost if the succus entericus has been previously boiled. Extracts of the intestinal mucous membrane also confer activity upon inactive pancreatic juice.

Benjamin Moore.

SUCRAMINE is a soluble ammonium salt of saccharin.

W. A. Bastedo.

SUET.—(*Sevum*, U. S. P.; *Sevum Præparatum* B. P.; *Sebum Ovile*, P. G.; *Suif de Mouton*, Codex Med.; mutton suet, mutton tallow. The Codex also recognizes the similar product of the ox, *Suif de Bœuf, Suif de Veau*, as well as the marrow, *Moelle de Bœuf*.) The part of the animal taken for suet is the same that yields the hardest and best lard, or beef tallow, namely, the thick mass of fat lying along the loins and surrounding the kidneys. The whole tissue is suet; the fat melted out and purified is tallow.

The preparation of suet is exceedingly simple, although not always carefully performed. It consists in first cleaning the suet from connective tissue, vessels, blood, etc., then cutting it in small pieces and washing in cold water, or allowing it to soak for a few hours in water; then it is boiled with a little water until the tissue is broken up, strained, and poured away to cool; the last portion of water is then removed by prolonged, moderate heat, which should not be allowed to rise above the boiling point of water. In the laboratory the steam kettles offer the most perfect means of "trying out" lard and tallow.

Mutton suet has no medicinal properties not common also to the other animal fats, excepting greater hardness, a higher melting point, and perhaps superior keeping qualities to most of them. It consists of the usual glycerin fats, *stearin, palmitin, olein*, etc., with the former in excess, and the latter at a minimum. The pharmacopœial description is as follows:

A white, solid fat, nearly inodorous, and having a bland taste when fresh, but becoming rancid on prolonged exposure to the air.

Insoluble in water or cold alcohol; soluble in forty-four parts of boiling alcohol, in about sixty parts of ether, and slowly in two parts of benzin. From its solution in the latter, kept in a stoppered flask, it slowly separates in a crystalline form on standing.

An alcoholic solution of suet is neutral or has only a slightly acid reaction to litmus paper moistened with alcohol.

Suet melts between 45° and 50° C. (113° and 122° F.), and congeals between 37° and 40° C. (98.6 and 104° F.).

Suet forms about one-fourth of mercurial ointment and one-half of tar ointment. It is also an extensively used domestic cerate.

Allied Substances.—Numerous fats of domestic and wild animals are in common household estimation for one purpose or another, with very little real difference from each other except in odor and hardness. Goose, chicken, and skunk oils are extensively used in country families all over New England. Something more distinctive, and having peculiar claims to attention, are the preparations of grease obtained from the wool of sheep, for which see *Lanolinum*.

W. P. Bolles.

SUGAR.—(*Cane Sugar, Saccharum*—$C_{12}H_{22}O_{11} = 341.2$, U. S., Ger., *Saccharum Purificatum*, Br., *Sucrose, Saccharose*.)

The refined sugar obtained from *Saccharum officinarum* L. and from various species or varieties of *Sorghum* (fam. *Gramineæ*); also from one or more varieties of *Beta vulgaris* L. (fam. *Chenopodiaceæ*).

Common sugar is one of a group of similar substances formed in plants and animals, distinguished by their sweetness, solubility in water and diluted alcohol, and insolubility in ether. Like starch, their function in the plant is nutritive. They represent carbohydrate nutriment, in a condition ready for use, as starch represents it in a condition for permanent storage, and they represent the latter substance in a transformed condition. Cane sugar is very widely distributed in the vegetable kingdom, being the variety generally characteristic of stems and roots. In a few plants the percentage is so large as to render the process of extraction and refining commercially profitable. The more important sources are as follows:

Saccharum officinarum L., the *sugar cane*, native of Southern Asia and cultivated in all tropical countries, is the most important. The yield of sugar from a good article is from fifteen to eighteen per cent. Comparatively recent operations in the development of new varieties from seed have resulted in the production of a much greater yield (up to nearly twenty-five per cent.), and the seedlings are in many cases far more vigorous and better capable of resisting disease than the old varieties, which were wholly the product of stem propagation.

Beta vulgaris L. (fam. *Chenopodiaceæ*) yields a number of varieties collectively known as *sugar beet*, which are especially rich in sugar, yielding upward of twelve per cent. For a long time the production of beet sugar was little more than an experiment, but recently the industry has made great strides and beet sugar has come to be a very formidable rival of that from the sugar cane.

Acer Saccharum Marsh. (*A. saccharinum* Wang,—non L.; *A. barbatum* Mich.), the *sugar* or *rock maple* of Eastern and Central North America, is next in importance to the above as a sugar producer in the United States. Maple sugar, as it is called, especially when somewhat imperfectly refined, possesses a peculiar flavor, aside from its sweetness, in which it differs from the other varieties of sugar here considered. This flavor, while not affecting its medicinal or pharmaceutical properties, renders it a great favorite with many persons for table use.

Sorghum sugar, formerly a very important article of domestic manufacture in the Central United States, has declined greatly in production, owing to the increasing cheapness of sugar cane and beet sugars. It is the product of *S. vulgare* Pers. (*Andropogon Sorghum* Brop.; *A. sativus* Hack.), of which there are many varieties. It is believed that broom-corn is merely a variety of the same plant. That which yields sugar is distinguished as *var. saccharatum* (L.) Gray. (*Holcus s.*—L.; *Andropogon s.*—Roxb.) This plant is often known as *Chinese sugar cane*. In tropical Asia and in other tropical countries considerable quantities of sugar are manufactured from *Saguerus Rumphii* Roxb. (*S. saccharifer* Bl.), often known as the *sugar palm*, from other species of palms and various other plants; but these products are rarely if ever articles of commerce in this country.

The official sugar is thus described:

White, dry, hard, distinctly crystalline granules, odorless, and having a purely sweet taste. Permanent in the air.

Soluble, at 15° C. (59° F.), in 0.5 part of water and in 175 parts of alcohol; in 0.2 part of boiling water and in 28 parts of boiling alcohol; also soluble in 80 parts of boiling, absolute alcohol, but insoluble in ether, chloroform, or carbon disulphide.

The aqueous solution, saturated at 15° C. (59° F.), has the specific gravity 1.345, and is miscible with water in all proportions.

The aqueous or alcoholic solution of sugar is neutral to litmus paper.

Both the aqueous and the alcoholic solution of sugar should be clear and transparent. When kept in large, well-closed, and completely filled bottles, the solutions should not deposit a sediment on prolonged standing (absence of *insoluble salts, ultramarine; Prussian blue*, etc.).

If 1 gm. of sugar be dissolved in 10 c.c. of boiling water, the solution mixed with four or five drops of silver nitrate T.S., then about 2 c.c. of ammonia water added, and the liquid quickly brought to the boiling point, not more than a slight coloration, but no black precipitate, should appear in the liquid after standing at rest for five minutes (absence of *grape-sugar*, or of more than a slight amount of *inverted sugar*).

PREPARATION.—The essential features of the manufacture of sugar are the rapid expression of the juice, the separation of impurities by various methods, partly mechanical and partly by precipitation, the evaporation of the water by boiling, the separation of the mother liquor or molasses (described below) and the crude sugar, and the refining and crystallization of the latter. These several processes may be performed by various methods. Although such modifications are frequently very slight, from a theoretical standpoint some of those of modern introduction are of so great an economic importance that they have completely revolutionized the industry, and their introduction into certain countries and not into others has even resulted in the complete ruin of the industry in the latter places. One of the most important of these series of modifications consists in the better use of lime or other alkalies for the purpose of neutralizing the acids present, which, under the influence of the heat in boiling, were formerly responsible for heavy losses in the yield of sugar through its conversion into invert sugar.

The large number of commercial varieties of refined sugar, depending as they do chiefly upon the degree of purification, the form and size of the crystals and of the fragments, the processes of powdering, coloring, and so on, are merely incidental and without pharmaceutical or medicinal interest. There are, however, certain of the sugar products which differ enough from ordinary crystallized sugar to be worthy of mention.

Barley sugar (*Saccharum hordeatum*) is sugar brought into the condition of a transparent, non-crystalline, yellowish body, as a result of melting and cooling. In this condition its taste is markedly different from that of the crystalline substance.

Caramel is an empyreumatic product made by keeping sugar at a temperature of 180° to 200° C. (356° to 392° F.) until it turns brown and loses two molecules of water. Caramel possesses a peculiar odor and taste, as well as a brown color, and is chiefly used for coloring purposes. It can, however, be decolorized, this product having been named *caramelan*.

Invert sugar is produced from ordinary sugar by various methods, most readily through the action of dilute acids under the influence of heat. It can also take place as a result of the prolonged action of heat alone upon a mixture of sugar and water. Invert sugar is a mixture of the two products dextrose and levulose, the latter not being capable of crystallization.

Rock candy is a very pure form of sugar, made to form in very large crystals.

The behavior of sugar under the action of certain ferments will be found considered under alcohol. Other changes produced in it are considered under the subject of digestion.

ACTION AND USE.—Sugar has been known from a very remote period in India, where the cane has been used as food from prehistoric times. It found its way into Europe about the beginning of the Christian era, probably as a natural exudation, like manna, from the wounded canes. It was originally an expensive rarity in Europe and used only as a medicine or luxury. Its general use there as a food dates back only two or three hundred years. Even at the present time, its consumption as a food is continually increasing upon a vast scale, partly because of the extension of its uses for preserving purposes, but chiefly on account of the continued cheapening of its price. It has no medicinal importance except for its slight expectorant properties (see below, under *Molasses*). Certain morbid conditions induced by its excessive or improper use are very general. Undoubtedly the human race would be far better off, so far as health is concerned, if the use of pure glucose could be generally substituted for that of cane sugar.

In pharmacy, the uses of sugar are varied, extensive, and highly important. As a preserver of some unstable chemicals, like iodide and suboxide of iron, fruit juices, and other perishable vegetable and animal products, it is invaluable. Mixed with water, it becomes a preservative solvent for many drugs, though if its strength be too greatly reduced it becomes readily fermentable. Its consistence frequently gives required body to preparations, and its taste is of the greatest value in many of its uses as an adjuvant. Finally, it is of great use as a coating for pills.

The only official preparation of sugar itself is *Simple Syrup* (*Syrupus*, U. S. P.), made by dissolving 850 gm. of coarsely powdered sugar in enough distilled water to make 1,000 c.c. It may also be made by the percolation of distilled water through sugar. Other official and unofficial syrups are to be regarded rather as syrupy preparations of the drugs themselves than as preparations of sugar.

Other Sugars.—Other kinds of sugar, animal and vegetable, will be found described in this work under the titles *Glucose*, *Honey*, *Manna*, *Milk*, *Sugar of*, as well as in connection with the liver, diabetes, etc.

Molasses or *treacle* is the mother liquor remaining after the separation of all the sugar which can be caused to crystallize after the boiling down of the prepared juice of the plant. The varying color, odor, flavor, and consistence of different varieties and grades of molasses depend partly upon the amount of sugar left in it, the degree of refinement and cleanliness observed in its preparation, and more or less purification to which it may be subjected. The practice prevails very largely at the present time of making molasses out of glucose, the latter chiefly manufactured from Indian corn, or of adding such glucose to natural molasses. Syrup, sugar-house syrup, or crystal drips, is a product of the final draining to which refined sugar is subjected.

In the household, the different varieties of molasses are credited with important and varied medicinal properties. Doubtless molasses or syrup has quite an important action in relieving an irritable cough, and many of the popular proprietary cough syrups probably owe the most of whatever value they possess to the influence of the syrup which they contain. *Henry H. Rusby.*

SUGARINE, methyl-benzoyl-sulfimid, methyl saccharine, is a compound said to have five hundred times the sweetening power of sugar. *W. A. Bastedo.*

SUGGILLATION (more properly *sugillation*, from *sugillare*, to beat black and blue).—In the older literature this term is used to designate superficial areas of discoloration, as black and blue spots, ecchymoses, hyperæmic spots, livid marks or patches, or various spots occurring in the skin in different diseases. The patches of discoloration in the skin of the cadaver due to post-mortem hypostasis or incipient putrefaction were likewise termed suggillations (*sugillatio*). More recently, through the influence of the German school, the term has come to be applied to hemorrhages into or beneath the tissues, of a larger size than ecchymoses; and with this usage there is also conveyed the idea of a *suffusion* of the tissues with blood. The term is, therefore, used interchangeably with *bloody suffusion*, and is applied to more or less flattened, diffuse swellings of the skin due to hemorrhage into the subcutaneous tissues, or to similar hemorrhages occurring in other loose tissues. A suggillation is distinguished from a hæmatoma by the fact that in the former the tissues are infiltrated with blood but not torn apart so as to form a distinct cavity filled with blood. Suggillations are usually due to direct trauma, but occur in cases of both congenital and acquired hæmophilia. In the latter case they may result from the changes produced in the blood-vessel walls through intoxication or infection. Suggillations of the skin may take place in pernicious anæmia, leukæmia, sepsis, chronic icterus, and in the hemorrhagic forms of the acute infections. In typhoid fever suggillations of the abdominal recti may occur as the result of extensive parenchymatous changes (Zenker's necrosis) in the muscle. The sequelæ of suggillation are similar to those of hæmatoma—absorption, organization, or cyst formation. *Aldred Scott Warthin.*

SUICIDE.—The term suicide, to express the act of self-destruction, was probably first employed by Desfontains in the last century. It is derived from the Latin words *sui* (self) and *cædere* (to kill). (Synonyms: Fr., *Suicide;* Ger., *Selbstmord;* It., *Suicidio;* Legal, *Felo de se.* Other rarely employed terms are: Gr., *αὐτοχειρία*; and Lat., *Propriicidium.*)

Suicide is a voluntary human act of self-destruction, and it is claimed by some writers that the act is always due to some disorder of the mind at the moment of its accomplishment.

History.—From the earliest times of which we have record the custom of self-destruction has existed to a greater or less degree, and it would appear that the peoples of antiquity were so taught by their religion that they could look upon the act as logical, and perform it with stoicism.

The religion of Brahma justifies suicide, and looks upon it, under certain conditions, as an honorable and praiseworthy act, which is often solemnized in a public manner. Fanatics in India, who believe in the transmigration of souls, seek an improvement in their condition and a freedom from present ills by courting death. The Brahmins have in a great measure given up their terrible custom of prostrating themselves before the car of their gigantic idol Juggernaut, to be crushed to death. Still they occasionally do it, and the women throw themselves upon the funeral pyres of their husbands.

Although held in honor among the people of the Orient, it was always rare in Persia, and is an exceptional occurrence among the Turks. The teachings of the Koran are opposed to it. Mohammed forbade it, and inculcated a spirit of patience in adversity. Here, too, the belief in fatalism probably exercised a marked influence, and the people were not given to philosophic thought, as were those of Greece, where many great men have sought death at their own hands.

When circumstances warranted the act, it was considered, in ancient Greece, a virtue for men to destroy themselves, thus escaping human ills, and, as they supposed, ameliorating their condition.

According to Legoyt,[1] Strabo relates as an historical fact that the inhabitants of the Isle of Ceos, in the Grecian Archipelago, poisoned themselves after reaching the age of sixty, so that the younger could have greater abundance; and Montaigne says that the senate of Marseilles, which then belonged to Greece, placed poison at the disposition of those who wished to commit suicide, when their motives were approved of.

The Hebrews, it would appear, scarcely knew suicide, and few cases are recorded. The Bible gives accounts of the self-destruction of Samson, Eleazar, Saul, Judas, and others.

The Celts were taught the immortality of the soul and their divine origin; still, suicide for the old and infirm was encouraged.

At Rome we find many noted suicides recorded, including that of Junius Brutus, and under the reign of Tiberius they appear to have increased in frequency. From the fifth to the twelfth centuries suicide almost wholly disappeared, but in the next century revolutionary ideas prevailed, and the previous influence of the Christian religion was so far lost that all classes of society suffered from a revival of suicide. Jews now resorted to it freely as a means of escape from hardships and to avoid disloyalty to their faith.

A decided increase is noted from the beginning of the sixteenth century, due to a disregard for religion and a revival of customs of antiquity.

In China and Japan men of honor have long resorted to self-inflicted death.

In Africa it was not rare for individuals and whole bodies of men to commit suicide, and Carthaginian generals often destroyed themselves after defeat.

The increase of suicide in civilized countries during the present century is shown by carefully gathered statistics, and conceded by most writers.

Statistics of suicide began to be systematically collected and studied only in the last century, official statistics being published in several European countries during the first twenty years of the century.

In Captain Graunt's "Bills of Mortality," published in 1665, it appears that 222 persons "hanged or made away with themselves" in the twenty years 1629–38 and 1647–58. This number, however, does not probably represent all the suicides, since there were probably a considerable number among the 827 registered as drowned, 243 found dead in the streets, and 14 poisoned. He estimated the population of London at that time as about 460,000.[26]

The following figures from the registrar-general's report for 1900 show that the suicide rate in England is increasing with a comparative degree of regularity:[3]

Suicides per Million Living, England and Wales, in Five-Year Periods.

	Rate per million.		Rate per million.
1861–1865	65.2	1881–1885	74.8
1866–1870	66.4	1886–1890	79.4
1871–1875	66.0	1891–1895	88.6
1876–1880	73.6	1896–1900	89.2

The following table presents the death rates from suicide per million inhabitants in the principal countries of Europe, and a few other countries, and in the six New England States:

Death Rates from Suicide in Different Countries per Million Inhabitants, 1880–1886; 1887–1893; and for the Single Year 1894.

Countries.	Estimated population in 1894.	Deaths from Suicide per Million Inhabitants.		
		1880–1886.	1887–1893.	1894.
Italy	30,818,248	47	54	56
France	38,133,385	196	227	?

* 1883-1886, four years only. † 1892-1893, two years only.
‡ 1896. § 1894-1899.

By the foregoing table it appears that suicides have increased in the greater number of countries shown in the table, but the length of time cannot be deemed to be sufficient to make the figures conclusive.[4, 15]

F. L. Hoffmann, in a study of the subject, found that the rate had increased, in fifty cities of the United States, from 120 per 1,000,000 in 1890 to 166 in 1901.[5]

The rate differs in these cities from a maximum of 499 per 1,000,000 in San Francisco to 29 in Fall River.[6]

The following list presents the suicide rates per million inhabitants in the year 1900 for cities having a population of more than 200,000:

Cities.	Suicides per million in 1900.	Cities.	Suicides per million in 1900.
New York	221	Pittsburg	121
Chicago	210	New Orleans	139
Philadelphia	114	Detroit	119
St. Louis	226	Milwaukee	207
Boston	135	Washington, D. C.	104
Baltimore	122	Newark	191
Cleveland	149	Jersey City	165
Buffalo	113	Louisville	98
San Francisco	499	Minneapolis	99
Cincinnati	135		

The following table presents the suicides for London, Berlin, Paris, Vienna, and Budapest:

Cities.	1895.	1896.	1897.	1898.	1899.	Annual average per million population.
London [3]	483	425	451	436	485	102
Berlin [23]	446	494	495	462	457	268
Paris [24]	1,030	941	1,004	906	788	372
Vienna [25]	427	429	440	450	463	284
Budapest [26]	227	196	260	261	....	375

According to the London *Lancet*, the number of suicides in France during 1876 was 5,617. Of these, 4,435 were men.

Morselli believes in a law of continual increase, and shows by a table that the increase per cent., from 1827 to 1852, was from 100 to 238.[2]

It is shown by one of his tables that Saxony, which furnishes the largest number of suicides, has suffered an increase from 158 per 1,000,000 inhabitants in 1836-40, to 391 per 1,000,000 in 1877, but the rate had decreased to 312 per 1,000,000 in 1894.

Another table prepared from the statistics of Italy, from 1864 to 1877, shows an increase from 29.2 to 40.6 per 1,000,000, and these had also increased to 65 per 1,000,000 in 1898.

The suicides in Italy were as follows for the five years 1894-98:[22]

Year.	Number.	Per million inhabitants.
1894	1,732	55
1895	1,874	60
1896	2,000	63
1897	1,895	60
1898	2,059	64

The highest rate was that of Liguria, 126 per 1,000,000 in 1898; and the lowest was that of Calabria, 12 per 1,000,000 in 1897.

In the German empire the suicides in the four years 1896-99 were as follows: 1896, 10,484; 1897, 10,692; 1898, 10,559; 1899, 10,418. These were equivalent to an average annual rate of 201 per 1,000,000 inhabitants.[9]

From these and other data the following law is formulated:

"In the aggregate of the civilized states of Europe and America, the frequency of suicide shows a growing and uniform increase, so that generally voluntary death since the beginning of the century has increased, and goes on increasing more rapidly than the geometrical augmentation of the population and of the general mortality."

In the combined central and southwestern states and provinces belonging to Prussia the proportion of 150 suicides in the million is given. Morselli says:

"The synthetic and most certain law which springs out of these facts is that in the centre of Europe, from the northeast of France to the eastern borders of Germany, a *suicidigenous* area exists, where suicide reaches the maximum of its intensity, and around which it takes a decreasing ratio to the limits of the Northern and Southern States."

NATURE.—The question of the nature of the act of self-destruction is a difficult and a delicate one withal to decide, but its great importance calls for much careful attention. Morselli says suicide is a social fact, and its nature "may now be reckoned among the most certain and valuable discoveries of experimental psychology"; and, further on, characterizes it as "an effect of the struggling for existence and of human selection, which works according to the laws of evolution among civilized people." But the question arises, is a given suicide, at the moment the act is committed, in the full and free possession of his faculties, and should he be held responsible for his movements? If the act be always due to a morbid condition of mind (as claimed by Dr. Liebman, in a paper read before the Medical and Chirurgical Faculty of Maryland, April, 1881), it should not be punishable as a crime; nor would, in this event, the punishment carry with it the intended restraining influence upon other would-be suicides. The mind which could conceive and plan so foul a deed would not, in all likelihood, be influenced by the thought of legal punishment in case of an unsuccessful attempt.

Insanity is probably present in the vast majority of suicidal attempts, and the number of those who act calmly and in the possession of their faculties must be much smaller than is generally supposed. Many obscure cases are difficult to explain on any other theory. There is a want of motive. The surroundings and station in life of the suicide are the best, and so far as can be learned, the social, financial, domestic, and other relations are only such as would be conducive to life and happiness. Such cases are more common in so-called epidemics of suicide. If the attempt has not resulted in death, evidences of insanity often soon appear, and make it clear that mental irresponsibility existed at the time.

In other cases insanity may have been previously known or suspected from conditions present, either immediately preceding the act or at some more remote period, and still no decided symptoms may have shown themselves until after an attempt at suicide.

An hereditary mental defect may have been known to exist, the person regarded as eccentric, and the attempt not unlooked for.

Organic disease, excesses, venery, onanism, etc., may have been the cause of a mental aberration whose first outward sign has been the suicidal attempt.

Hammond says:[10] "Closely allied to emotional homicidal impulse is that form of mental derangement which consists in an *emotional impulse to the perpetration of suicide*. The conditions may coexist. In some cases the contemplation of the act is attended with feelings of pleasure. He is neither governed by delusions nor by logical reasons. He is actuated by a passion which it is pleasant for him to gratify. When the impulse has passed, he looks back upon it with horror, and, shuddering at the escape he has made, perhaps seeks medical advice."

Automatic suicide, or suicide by impulse, is closely allied to that of the insane, and, like it, occurs without apparent cause—the sight of a weapon, the finding of one's self upon a height or by the river's side, or favorably situated for the accomplishment of the act, being sufficient for the attempt. In non-success the circumstances of the act are more or less confused in the suicide's mind, and the only safety for those thus impelled is to hasten from the scene. Some persons, appearing to be conscious of this outward influence, avoid suggestive situations, and, feeling themselves powerless to resist, ask that precautions be taken to prevent the act.

Suicide by suggestion is well illustrated in a personal experience of Sir Charles Bell, when surgeon of the Middlesex Hospital, which is related by Wynter.[11] While being shaved, he told his barber of an operation he had just performed on a man who had made an unsuccessful attempt to cut his throat, and explained the anatomical reasons for the failure. The barber, excusing himself, went into an adjoining room, and was found a few moments later with his throat cut in the proper anatomical situation to assure success.

Epidemic suicide, due to a neuropathic state of the system of those living under the same influences, is well known to neurologists, and many instances have been observed. An epidemic among the women of Miletus is recorded, at a time when the men were away at war, which reached great proportions and was checked by a decree that the naked bodies of those who killed themselves should be exposed in public with a rope about the neck. In Mexico and Peru the inhabitants killed themselves in great numbers, it is said, after the invasion by Spain. Mansfeld had an epidemic in 1697, according to Sydenham. There was one at Versailles in 1793, and one occurred at Rouen in 1806, and at Stuttgart in 1811.

Some years ago five inmates of the Hôtel des Invalides, in Paris, hanged themselves upon the same crossbar within a fortnight.

Double and *multiple* suicides are occasionally recorded. The former usually consisting in the simultaneous death of man and wife, or two lovers or friends; the latter in the concordance of suicide of bodies of men, such as is said to have occurred in China among the philosophers of the Confucius school, when deprived of their books by the order of the emperor Chi-Koang-Ti.

Feigned Suicide.—Although the term is not a strictly proper one, it applies to those cases occasionally met with in which, to excite sympathy, secure desired ends, afflict friends, or for some other reason, a person makes it appear that he has made an attempt upon his own life.

Child suicide requires special notice, since young children, even as young as five years, have been known to commit suicide for trifling cause, following impulse and sentiment without having the restraining influence of mature judgment and the power of comparison and thought for anything beyond the present.

By nature children are sensitive to slights and injustice, easily depressed, fretful under restraint, and at times revengeful. They have vivid imaginations, are quick to imitate, but are defective in the power to reflect and form just conclusions. The sense of responsibility is wanting, so that no sooner is the act conceived than it is put into execution.

The belief of Durand Fardel,[12] that the act of self-destruction is usually accomplished with much self-possession and after reflection, cannot apply to suicides in childhood (see, also, under *Age*).

Suicide following homicide is not very uncommon, but the subject is almost always melancholic. Esquirol tells of a Belgian woman who threw her four children into a well and jumped in after them. Both sexes include their children in the death they give themselves, but women would appear more inclined to this than men. In rare cases both parents conspire to kill their children and then themselves; such a case is related by Esquirol, and one has recently occurred in Paris.

CAUSES OF SUICIDE.—In former times, and indeed at the present day in some countries, as we have seen, whole masses of people, as well as individuals, under the influence of their religious or philosophic beliefs, and following the customs of their forefathers for generations, have in great numbers become the subjects of self-destruction. No such custom is to be found to-day in any civilized country, but efforts to do away with it in India have failed, and we must put down fanaticism as one cause of many self inflicted deaths. No encouragement is given to the act in enlightened lands, but, on the contrary, laws, both human and divine, are strict in forbidding it. Still, suicides have been shown by careful students of the subject to be on the increase, and we naturally inquire what are the causes which contribute to this state of affairs, and why do men take their own lives at all.

The causes are twofold: A subjective condition may exist which predisposes the individual to the act, or his environment may be such as to produce an objective state favorable to suicide. The pathological or other subjective condition may coexist with the surroundings which furnish the determining cause, or the one or the other may be wanting.

Predisposing causes to suicide are quite numerous, but heredity is one of the most important. The transmission of a suicidal tendency is an established fact of which many instances are known to alienists, and which forms a familiar phase of the practice of the family physician.

This transmitted tendency may lie dormant, or make its presence suspected by the development of mental disease; or the suicide may have been looked upon for years as one about whom there was "something strange," without any actual disease or decided symptoms of nerve or mental trouble being apparent.

The offspring of a suicidal parent appears to inherit a system favorable to the development of nervous affections leading to self-destruction, and a decided tendency appears to exist to commit the act at about the same age at which the parent died, and to use the same means; showing that the hereditary disposition is attended with a certain uniformity of action.

Education would appear to predispose to suicide, for it has been conclusively shown that more attempts occur in centres of civilization, among the best educated classes, and in cities where, through the press, pulpit, and stage, as well as through educational institutions proper, the masses of the people are better informed than those in the country, and, as a rule, have more active minds; but in whom the conditions of life are more apt to favor a spirit of discontent. Among savages suicide is comparatively rare. Among the whites in the United States, according to the census of 1900, the suicides were 5,340 as compared with 149 among the negroes, the actual death rate from this cause being about five times as great among the whites as among the colored.[13]

Occupation appears to have a predisposing influence. Thus the trades in which the greatest number of suicides occur are shown to be those of tailors, seamstresses, laundresses, jewellers, carpenters, cooks, etc. The hardships of life attending many of these occupations may account for the number of deaths.

Wine merchants and innkeepers make large contributions to the number of suicides, because their occupation tends to induce excess in the use of alcohol.

The liberal professions furnish about one-fifth of the total number of suicides; physicians, chemists, and druggists give a high percentage, and their occupations may be said to predispose to it by bringing them into such constant and intimate relations with poisons.

The stringency of military discipline in Germany, France, and Austria has been advanced as a reason for the high death rate from suicide in these countries.

Morselli finds the greatest number of suicides among (1) literary and scientific men, or brain-workers generally, professors, teachers, etc.; (2) the military; (3) workers in the trades.

According to Legoyt (1856–60), the middle classes and outcasts furnish the greatest number in France, and the same is found by Block to hold true (p. 251).

The condition of life has its influence as well, and those living solitary lives, as widowers, bachelors, divorced women, etc., are more prone to the act. By the census of 1900 it appears that there were in that year 1,620 suicides among single persons, 2,832 among the married, 560 who were widowed, and 41 who had been divorced.[13]

Religious Belief.—From a large collection of cases in Germany and Austria it appears that the suicide rate among Catholics was 51.3 per 1,000,000 living, among Protestants it was 79.5 per 1,000,000, and among Jews only 20.7 per 1,000,000.[14]

Climate and temperature in many instances undoubtedly contribute their share, but the attempts to regard them as the main cause of a high percentage of suicides in some countries have not been eminently successful. The cold, rain, and fog of England have, by various writers, been regarded as conducive to self-destruction. Thus, Montesquieu said, "England is the classic land of suicide"; but in Wynter we read ("The Borderland of Insanity," 1875), "Paris is the headquarters of self-destruction."

Putting aside the compliments that may be passed between these two countries, we must remember that the Esquimaux and Falkland Islanders, whose climate is incomparably more severe than that of either of these countries, do not kill themselves.

The influence of climate is, on the whole, not marked, but excessive heat has been known to drive men to frenzy and self-destruction. Long since it was pointed out that the hot and dry wind of the African sirocco caused delirium, madness, and many suicides.

Seasons.—In most countries the maximum of suicides is reached in May and June, when nature would seem to be most conducive to life. In Saxony and Bavaria, however, July is the favorite month.

Authorities agree that insanity increases in the summer time, and this may explain, as Wagner thought, the greater number of suicides. Leffingwell presents a table in which he shows that for the ten years (1878–87) the suicides in the warm months (April–September) constituted sixty per cent. of the whole number, and those in the cold months were forty per cent. A similar table for Japan for the years 1882–85 gave the same result.[15]

Sex.—In a general way, the average of female suicides for the United States is given as from fifteen to thirty per cent. of the whole number. In 1900, according to the United States census, suicides of women constituted 21.5 per cent. of the whole number of suicides in the United States.[13] Liebman says three men kill themselves to every woman.

The proportion of women is given for Germany as under, and for England as over, twenty per cent. As accounting for this excess of male suicides it has been advanced that women have less energy, less resolution, are more governed by religious teachings, etc. The suicides of males in England were 101 per 1,000,000 in 1875 and had increased to 137 per 1,000,000 in 1899, while those of females were 34 per 1,000,000 in 1875 and had increased to 44 per 1,000,000 in 1899.[7]

Age.—Considerable regularity is shown, in each country, in the number of suicides at each age-period of life. From Ogle's table, as well as from those of Morselli, it is seen that, from the tenth year on, the number of cases rises steadily to between the ages of fifty five and sixty-five years; remains almost stationary to about seventy-five, and then decreases rapidly. It is rare before fifteen, but, excepting the very young, it is common to all periods of life.

The period from the twentieth to the fiftieth year has the most instances, for it is then that men pass through the most serious portion of their lives. It is then they are engaged in the battle for existence, require more comforts, and have most care and responsibility.

According to Ogle, 1 out of every 119 men who reach the age of twenty ultimately dies by his own hand, and 1 out of every 312 women who have reached the age of fifteen.

Attempts upon their own lives have been made by children at as early an age as five years. Durand Fardel found one under five, and two between eight and nine. Out of 25,760 suicides in France occurring from 1835 to 1844, he found 192 to be in persons under the age of sixteen.

According to the census of 1900 the suicides in the United States in that year occurred as follows:[13]

Ages.	Suicides.	Ages.	Suicides.
5 to 9	1	50 to 54	490
10 to 14	28	55 to 59	371
15 to 19	246	60 to 64	314
20 to 24	531	65 to 69	253
25 to 29	534	70 to 74	175
30 to 34	555	75 to 79	117
35 to 39	594	80 to 84	49
40 to 44	600	85 to 89	14
45 to 49	542	90 and over	5

The suicides in the German Empire by ages were as follows in 1892:[28] Under 15 years, 7 per 1,000,000 living at that age; from 15 to 60 years, 280 per 1,000,000; over 60 years, 510 per 1,000,000.

Collineau[16] relates the case of a boy ten years of age who, "to make his parents angry," hanged himself on being sent back to school.

Winslow[17] reports several cases at an early age, and quotes Casper to the effect that in Berlin, from 1812 to 1821, 31 children, twelve years of age and under, committed suicide for trifling causes. Many cases at this early age appear to be similar to the emotional susceptibility of adult life.

Suicide is an act which springs from a brain constantly influenced by conditions present within the body, as well as by those of the external world, many of which we have considered as predisposing causes.

Determining Causes.—Insanity with suicidal tendency is quite a common form of mental disease. It is not proposed to enter upon a consideration of the various forms of insanity in which this tendency is present. We may find it as a monomania, or associated with a homicidal mania.

It is often by suicide that the melancholic rids himself of his imaginary woes, and the maniac escapes from the imaginary foes with which his hallucinations surround him.

There are those who claim that the act of suicide is of itself an evidence of insanity. In the maniac there is no planning, and no precautions are taken; violence is characteristic of the act, and it is as a rule accomplished quickly. Should it fail, there is a knowledge and recollection of the details. Death may accidentally result from the attempts of the maniac to escape from hallucinations or in his efforts to free himself from restraint. This should not, properly speaking, be termed suicide, for although it is self-destruction, there is no intention or motive, and the term, as commonly used, implies a purpose.

In some insane persons there is an ever-present hallucination attended with a morbid sadness, and the act of suicide is deliberately planned and, with much precaution and calmness, carried into execution; or, if not at once successful, it will be persisted in until it is.

There is a form of anxious melancholy in which, without any cause, either real or imagined, there is, as it were an instinctive but violent desire to die; so strong, indeed, is it, that no will-power seems capable of overcoming it. The previous anxiety is lost when all preparations are made and the desired end appears near, and this sudden change to cheerfulness may give friends and attendants the cue to watch for the attempt.

As a rule, determined and deliberate attempts at suicide, with details carefully planned, indicate an unsound mind. When the attempt has failed to cause death, it is often found that insanity soon appears. In other cases the attempt itself relieves the condition which caused it, and death is no longer desired.

The flow of blood from a razor wound, Hammond says, may relieve the cerebral congestion present. In the same way, a plunge into the cold water may result in bringing the would-be suicide to a realizing sense of his desire for life rather than for death.

Others, to assure success, may tie their own hands and feet together before making the plunge, and may even attach weights to themselves, as in the recent case of a young actor who, before plunging into the Charles River, in Boston, put on a heavy coat of mail; and of a man who jumped from a Brooklyn ferryboat with lead-pipe wound round and round the body. The possible occurrence of such cases must be remembered in medicolegal and coroner's investigations, and not be mistaken for cases of murder. Financial ruin, famine, and pestilence following in the train of wars, etc., have often resulted in great numbers of suicides, the nervous system being over-excited.

Disease, as an inciting cause of the suicidal act, is not uncommon. The body, worn out with suffering, at last affects the mind, or the patient, believing his disease incurable, prefers to make an end of all his woes, and "fly to others which we know not of."

Statistics for Italy and France show that those affected with pellagra furnish a large percentage of suicides. Other diseases in which suicide appears to be common are those of the digestive organs, liver, etc., cancer, urinary diseases, phthisis, loss of sight, and chronic affections generally; after castration it appears also to be frequent. Suicides through physical suffering attain their maximum in the educated and cultivated classes.

Financial troubles cause the highest percentage among the working classes, though self-destruction is often seen after reverses of fortune, losses in gambling, and financial embarrassment in the wealthy.

Alcohol is a potent cause of self-inflicted death; drunkenness, poverty, and laziness going hand in hand. In the three years 1888–90, in Massachusetts, 93 suicides out of a total of 485, or 19 per cent., were due to intemperance.[18]

Passions.—Love, betrayed or disappointed, and jealousy are found to be a fruitful cause of suicide among students, soldiers, schoolmistresses, and servants. Explosions of rage and anger are apt to gradually increase and overcome the will power to resist, until trivial circumstances will occasion violent outbursts, and may lead to violent acts against one's self. Hate, pride, shame, and revenge may all lead to suicide.

Other determining causes often found are domestic troubles, remorse, dishonor (as in women pregnant out of marriage), poverty, misfortune, grief, pain, and disappointment.

Occasionally regret is experienced before the act has been fully accomplished.

METHOD.—The method of securing death, and the place or scene of its execution, are influenced by the surroundings of the individual and the natural facilities afforded; but the supposition advanced by Esquirol, that the occupation governed the choice of instrument, is not always borne out by statistics. Still, it is found that the choice of the soldier falls, as if in theory it naturally would, upon firearms. Butchers, barbers, and shoemakers resort mostly to the knife. The favorite method varies in different countries, and although in a given locality or city the prevailing custom may change from time to time, there is a pretty constant preference for one fixed form from year to year. De Guerry[19] was the first to show a regularity in the method employed.

The rope appears to be the most common choice, second comes the water, firearms third, cutting instruments fourth, then follow jumping from a height, taking of poisons, inhalation of deadly fumes, etc.

There are two factors which, as a rule, influence the choice of the means, viz., certainty and quickness of action. Women are not so apt as men to make choice of a painless method.

There is also a difference in the means employed by women from those resorted to by men. In Italy, for example, the men shoot themselves, and women resort to the water when weary of life; while in Prussia over half the suicides die by hanging, and women surpass the men in their tendency to kill themselves by the knife.

Out of 2,896 suicides which occurred in England in 1900, 102 were upon railways, 690 were by gunshot wounds, throat-cutting, etc.; 10 by burns and explosions, 454 by poisons, 695 by drowning, 792 by hanging, 68 by jumping from a height, and 84 by other methods.

The poisons preferred were in the following order: Carbolic acid, 134; preparations of opium, 69; oxalic acid, 47; hydrochloric acid, 42; prussic acid, 36; strychnine, 17; cyanide of potassium, 16; phosphorus, 8.[3]

In Massachusetts suicides by the use of arsenic had increased from 2 in 1878 to 35 in 1887, but had again fallen off to 9 in 1899 and 6 in 1900.[15]

Poison, as a choice, appears to be increasing in favor in this country, and to be on the decline in France; in fact, the favor it receives among Anglo-Saxon suicides is shown to reach 40.8 per cent., including this country. Out of 148 cases of suicide occurring in New York in the year 1876, poison was used in 31.7 per cent., firearms in 33.1; hanging gave 13.5; cutting wounds, 10.8; drowning, 6.8; falls from height, 3.4; and other means, 0.7; thus showing that poison and firearms were the choice, each in about one-third of the cases. This predilection on the part of the English and Irish for poisons is further shown by the following table, taken from Morselli, and giving the suicides among foreigners in New York for the year 1876:

Per 100.	English.	French.	Germans.	Irish.
Poisoning	46.1	25.0	28.9	52.4
Hanging	....	12.5	17.4	4.8
Asphyxia and drowning	....	....	5.7	9.6
Gunshot wounds	15.4	50.0	35.0	4.8
Cutting and stabbing	30.8	....	7.2	9.5
Falls from height	7.7	12.5	5.8	18.9
Total	100.0	100.0	100.0	100.0

The following were the methods employed by suicides in Paris for the five years 1895–99:[24]

Poison	192	Cutting instruments	69
Asphyxia	1,075	Jumping from a height	265
Strangulation (hanging)	1,310	Crushing, railroad	19
Drowning	988	Other modes	4
Firearms	747		

The following figures show the methods adopted in the United States in 1900 (United States Census):

	Males.	Females.
Shooting	1,190	103
Drowning	157	84
Poison	761	464
Other methods	2,205	534
Total	4,313	1,185

The methods employed at different ages present striking differences, according to the United States Census of 1900, where it appears that at ages 15–24, 168 females and only 95 males committed suicide by poison, while at ages 50–59, 184 males suicided by shooting, and only 7 females.[13]

Drowning as a means decreases as the north is approached; the colder the water, the fewer its attractions.

Devergie found that in Paris, from 1827 to 1836, drowning, together with asphyxia by charcoal fumes, held the second place, but in 1851 Trébuchet placed asphyxia at the head of the list. This latter mode of death has spread rapidly over Europe and increased in fashion in Paris. The reasons for this are that it affords the most painless and agreeable form of death, and, strange as it may appear, man's vanity extends beyond the gates of death, and the suicide desires the body to present a good appearance after the breath has left it, and knows that there is usually no disfigurement from charcoal fumes.

The introduction of a new and easy method of committing suicide affects the numbers by different methods. Previous to 1890 the extremely poisonous agent, water gas, was excluded from Massachusetts by law. After the repeal of this law in 1890, its use became free and unrestricted, and the suicides by gas poisoning increased from a total of 5 out of 915 by all methods in the five years 1886–90, or 0.55 per cent., to a total of 116 out of 1,575 by all methods, or 7.4 per cent., in the five years 1896–1900, an increase of nearly fifteenfold.[18]

Only the other day the papers contained an account of a "wholesale charcoaling," in which a father, mother, and two children sought death in this way, preferring this mode of death to starvation. When heredity is a factor in the case, the method of exit from the world is apt to be the same as that employed by the ancestor.

Winslow says that one manner of death having been conceived, the man bent on suicide will wait a long time until he can carry out his particular plans. We, however, often see a man who has failed in one way take the first opportunity to secure death in another. Maniacs are most apt to throw themselves from a height, and it is often difficult to say whether one who has fallen from a window did so in simply making an attempt to escape imaginary enemies, mistaking the window for a door, or possibly walked out without any knowledge of the act, or was conscious of the attempt. Some inflict wounds upon themselves, or severely injure the head by pounding it against the wall, impelled by their pains to seek this means of gaining relief. Melancholics often hear a voice urging them to take their lives, and this "voice" at times suggests the means.

Place.—Much ceremony attends the act in some individuals, and publicity is sought. This is often done when revenge is intended. Usually, however, suicides occur in privacy, and it is not uncommon for a man to retire to a concealed and unfrequented spot to carry out his object.

Particular places may become, as it were, fashionable for a time in the suicidal world. Thus, one year, in Paris, the Arc de Triomphe, another Nôtre Dame steeple, and another one of the bridges, will be the favorite leap. The Milan Cathedral, St. Peter's at Rome, and the Campanile at Florence have all in turn had their epidemics, so to speak. So also have the Brooklyn Bridge and Niagara Falls in America.

Esquirol[20] relates a very remarkable method which was employed in a case reported by Dr. Ruggieri,[21] an Italian, which shows what an amount of self-inflicted torture will be endured. A shoemaker in Naples, who had the year before castrated himself and thrown the genitals from the window, after making a good recovery, conceived the idea that God had commanded him to suffer on the cross. He passed two years in perfecting his plans, which were so well carried out that one morning he was found with hands and feet securely nailed to a cross, with a stab wound in the left side, hanging out of his bedroom window. He had constructed the cross and attached it by ropes in such a way that after crucifying himself he could, by motions of the body, cause it to slip from the window. When rescued he was delirious, and although he recovered from his wounds, he exhausted himself by fasting and died.

A novel method has just been introduced in this country, by an anarchist, of exploding a dynamite cartridge in the mouth, bearing out Esquirol's claim that the instrument chosen was apt to be the one which the suicide used professionally.

Time.—The time of day most favorable to acts of self destruction appears to be between the hours of six and twelve in the morning. This preference for the early part of the day extends to the other divisions of time, for it has been found that more suicides occur in the forepart of the week and the first half of the month than in the latter parts.

SYMPTOMS.—It is questionable whether we can say that there are any actual symptoms by which an act of suicide can be predicted. In insanity, and especially in melancholia, an attempt must always be watched for.

In some cases a man, who has been previously healthy, will complain of pain in the epigastrium, of heaviness in the head, will become quiet, listless, lose all ambition, refuse to work or attend to his usual vocations; the habits are changed, and intoxication may be indulged in. There may be scarcely any other symptoms until he tries to cut the thread of life. Weariness of life is often complained of, but Esquirol says he has never seen any attempt because of this *tædium vitæ* alone.

Some individuals predict that they will some day kill themselves and eventually do, but as a rule the one who threatens the act rarely commits it.

In some cases it may be discovered that preparations are being made for death, associated with a sadness of expression and an uneasiness of action. In melancholia the opposite condition may prevail just before the attempt, when all the plans are laid. The skin of suicides has been said to assume a yellow tinge and the features to become shrivelled, giving a changed appearance at the same time that a change is noticed in the actions.

Anæsthesia is a marked symptom at the actual moment of the attempt in many cases, and it is said that after the skin is cut the pain in cutting the throat is not at all severe. This accounts for the little complaint or appearance of pain in cases which, it would appear, must have been attended with torture.

DIAGNOSIS is important in a medico-legal sense, as we have seen that few signs or symptoms of value precede the act. A knowledge of previous attempts will aid us, and at times a hint may be given by some word of the individual or by an ante-mortem letter.

If the attempt has failed the fact may be acknowledged; if death has resulted, writings are to be looked for. The body is to be examined for lesions, especially in the vital regions. The direction of bullet and penetrating stab wounds is to be carefully noted, and the existence or absence of powder marks upon the skin, and wadding, pieces of clothing, etc., within the wound. If death has resulted from a sharp weapon, signs of violence must be looked for upon the body and in its surroundings. The employment of a razor, although favoring a theory of suicide, is not to be regarded as conclusive, because in this country it is quite a favorite weapon with the negro race. If the razor can be shown to belong to the individual, the suicide theory is strengthened.

If poison has been taken, a bottle or paper which has contained it may be discovered near the scene. Though most men found hanging are suicides, the possibilities of lynching and of hanging a dead body to hide a crime must be remembered. In the case of bodies found in the water, great care must be exercised in giving true significance to wounds, and determining whether they were inflicted before death. The fact that the limbs are tied has not great weight, for the suicide might have thought thus to assure success, and even have attached weights to the body.

Pathological lesions found on autopsy shed but little light on the subject of suicide.

PROPHYLAXIS.—Cannot something be done, we instinctively ask, to prevent so great a number of human beings from committing so heinous an act? Something at least to prevent the ever-constant increase? The solution of the problem must lie largely in the better care of the insane, and earlier and more scientific treatment of mental diseases. Hospitals properly equipped for the treatment, supervision, and restraint of the mentally weak and infirm, and the disappearance of the popular prejudice against insane asylums, will do much to decrease the number of suicides in this large class.

Legislation.—In epidemic suicide and in alarming increase of the act, it has been found necessary to enforce stringent laws against the bodies, property, and families of the suicide at various periods of the world's history, and at times with some apparent success.

Laws were established in regard to suicide at a very early day. Zeno's motto, which was such a favorite phrase of the Stoics, "*Mori licet cui vivere non placet,*" was found not to have an application to the individual whose act caused injury to others and loss to the state. It was opposed to the teaching of the Bible, which says, "Thou shalt not kill."

Esquirol thinks some threatening law against the individual should be enforced with reference to the social usages of the people of each particular country. He says comminatory laws have caused suicide to cease in Egypt and Miletus.

Legislation, though not powerful to accomplish much, should nevertheless exist. It will undoubtedly deter a few, and this alone will prove its usefulness.

The attempt at suicide is punishable in New York State by five years' imprisonment, according to existing laws recently enacted.

The confiscation of property and denial of the right of burial, formerly practised in France, have of late years been stricken from the Code.

Formerly, in England, the body of a suicide was treated with ignominy, buried in the highway, and transfixed by a stake. When this law was abolished, the body could still only be buried at night and without religious rites. The canons of the Roman Catholic Church still forbid the burial of a suicide in consecrated ground.

The laws of antiquity, severe as they were upon the family, name, and possessions of the individual, had but slight effect in repressing suicide, as would naturally be expected in the case of the insane, who contribute most largely. In some countries the bodies of all suicides are given for dissection.

The public press has it in its power to favor an increase in suicide by publishing, with minute details, descriptions of all suicides, thus exciting depraved tastes, pampering to the vicious, and putting ideas regarding the act into the minds of nervously weak and predisposed persons. Fortunately, this tendency is much less marked than at a former period, but the danger should be constantly pointed out and guarded against when suicides become at all frequent in a community.

Silence is the antidote for this form of nervous, imitative suicide, as Moreau has aptly and truly said.

TREATMENT.—When a tendency to self-destruction has been discovered, moral treatment may be of much benefit. Kindness, cheerful attention, and society, and the assurance of aid and support, may brighten hope. Argument and sympathy have never done good. When an individual threatens to kill himself, the best treatment is probably to tell him to go ahead and do it. This usually results in a cessation of the threats.

Those mentally afflicted should be placed in institutions, and it has been recommended that all having suicidal tendency be placed together, at least at night, and this plan is carried out in many of our institutions. Tonics and sedatives are usually called for, and remedies suited to the physical derangement, whatever that may be.

SULFOSOT is a syrup containing about five per cent. each of guaiacol and cresol sulfonates of potassium. These are obtained by treating creosote with concentrated sulphuric acid and combining with potassium. The remedy is used for tuberculosis in dose of 4 c.c. (ʒ i.).

W. A. Bastedo.

SULPHAMINOL.—An antiseptic formed by the action of sulphur upon certain salts of the aromatic series. In the body it is supposed to decompose into carbolic acid and sulphur compounds. It was introduced for the purpose of replacing iodoform, on account of its active antiseptic action and freedom from odor. It is a pale yellow powder, without taste or odor, insoluble in water but dissolved by the addition of alkalies; it is soluble in alcohol. When subjected to heat it turns brown and melts at about 155° C. The dose for internal administration is four grains three times a day, but it does not appear to have been used to any extent.

Externally, it has been used in all cases in which iodoform is employed.

Beaumont Small.

SULPHIDES.—Sulphides of four metallic bases occur among medicines, namely, sulphides of *mercury, antimony, potassium*, and *calcium*. Of these, the sulphides of mercury and antimony are, medicinally, not specifically peculiar, and will be found discussed under the titles of the several metals. The sulphides of the other two bases exhibit marked properties, evidently due to the sulphur of their composition, and accordingly form a distinct group of medicines. The common characteristics are, physically, an alkaline reaction, a disagreeable smell, and an alkaline and offensive sulphureted taste; physiologically, quite intense, irritant properties, and a special obnoxiousness to animal and vegetable skin parasites; and, therapeutically, a local healing influence over many skin diseases in their chronic stage, and, given internally, an uncertain tendency to abate chronic glandular, or cutaneous, or arthritic disease, and to control or repress suppuration. In full dose too long continued, the compounds tend to impair general nutrition, leading to emaciation and muscular weakness. Following are in detail the pharmaceutical preparations containing the sulphides in question, with their special properties and uses:

POTASSA SULPHURATA: *Sulphurated Potassa.*—This is an official preparation of the United States Pharmacopœia, made by heating in a covered crucible, to melting, a mixture of dried potassium carbonate and sublimed sulphur. The product solidifies upon cooling, and is then broken into pieces and put up in well stoppered bottles of hard glass. Products obtained by the foregoing general process are commonly called, generically, *hepar sulphuris* (liver of sulphur), the name being expressive of the color. Such products are composite bodies, but the composition varies according to the degree of heat to which the mixture of potassium carbonate and sulphur has been subjected in the preparation. By the comparatively low heat directed in the United States pharmacopœial process, the product is probably a mixture of potassium hyposulphite and trisulphide ($K_2S_2O_3 + 2K_2S_3$). At a higher heat, such as is used in the British pharmacopœial process, the hyposulphite first formed splits into potassium sulphate and pentasulphide. When freshly made, sulphurated potassa appears in irregular, liver-colored lumps, which, on exposure to the air, gradually absorb oxygen, carbon dioxide, and water, and change color to a greenish-yellow. Finally they turn into a gray material containing potassium carbonate, sulphate, and hyposulphite. Liver of sulphur dissolves, all but a small residue, in two parts of cold water. Alcohol dissolves the potassium sulphide, but leaves undissolved the other component substances of the preparation. Sulphurated potassa should contain at least fifty-six per cent. of potassium sulphide. It is decomposed by mineral acids, and by most solutions of metallic salts.

Sulphurated potassa possesses the general properties detailed above; it is violently irritant, even to corrosiveness, and overdosage may easily kill by excessive gastrointestinal irritation. The medicine is used, locally, to kill parasites, and to favor the healing of skin disease or the abatement of rheumatic or gouty troubles, and, internally, to assist in the two latter-named operations. The parasiticide action is utilized mainly for the destruction of the itch insect, for which purpose this compound is exceedingly efficacious. The preparation is applied locally, in the form of ointment, lotion, or general bath. For an ointment of proper average strength, sulphurated potassa may be mixed with lard in the proportion of six per cent. of the former; for a lotion, an aqueous solution ranging from three to six per cent. in strength may be used; and, for a bath, about 125 gm. (four ounces) may be dissolved in about 120 litres of water (about 30 gallons). Concentrated applications never should be made, because of the sharp irritation which would result. Baths containing sulphurated potassa (commonly spoken of as *sulphur baths*), besides their foregoing use, are sometimes employed in the treatment of chronic lead-poisoning, because of the finding that patients suffering from lead contamination show upon their skins, after immersion in a sulphur bath, a dark discoloration, as from the forming there of lead sulphide. The inference is that the sulphur in some mysterious way coaxes the lead out of the system through the skin emunctories, in order to satisfy its chemical longing for a union with the metal. Sulphur baths are administered warm or hot, and of a duration from half an hour to two or three hours. They are apt, particularly when protracted, to produce a good deal of irritation of the skin, even to the development of a papular or vesicular eruption. These baths should be prepared in wooden tubs. For internal giving, the dose of sulphurated potassa ranges from 0.12 to 0.40 gm. (two to six grains), several times a day, given in pill or in some aromatized syrup.

CALX SULPHURATA: *Sulphurated Lime.*—The preparation thus named in the United States Pharmacopœia is what is commonly, but incorrectly, called *sulphide of calcium.* It is a mixture in varying proportions of calcium sulphide, calcium sulphate, and carbon, but should contain at least sixty per cent. of calcium sulphide—the salt which gives the substance its medicinal activity. Sulphurated lime is made, by the process directed in the United States Pharmacopœia, by heating to a bright red heat in a closed crucible a mixture of dried calcium sulphate, charcoal, and starch. The product, after cooling, is pulverized, and at once put up in small glass stoppered vials. It appears as a grayish-white or yellowish-white powder, which slowly decomposes on exposure to the air. It has a faint odor of hydrogen sulphide, and an offensive and alkaline taste. It is alkaline in reaction, is very slightly soluble in water, and insoluble in alcohol.

Sulphurated lime, like sulphurated potassa, has the general properties of the alkaline sulphides, as already detailed. It is powerfully irritant, even medicinal doses being apt to upset the stomach. And it is a disagreeable medicine for internal taking, also, because of its giving rise to eructations of sulphureted gases. The preparation has been used, locally, principally as a depilatory. For this purpose it is applied in powder, and, after fifteen minutes, the part is wiped with a wet sponge. Medicine and hairs then come away together. Internally, sulphurated lime has acquired a certain reputation as tending to control suppurations, the discharge lessening in quantity and offensive pus acquiring a better character under the medication. Given between times in recurring suppurations, as in recurring crops of boils, it is also held to abate the frequency and severity of the attacks. The dose of sulphurated lime ranges from 0.003 to 0.006 gm. (gr. $\frac{1}{20}$ to gr. $\frac{1}{10}$), several times a day, or even hourly, given most conveniently in trituration with sugar of milk. *Edward Curtis.*

SULPHITES AND "HYPOSULPHITES" (Thiosulphates).—I. GENERAL MEDICINAL PROPERTIES OF SULPHITES AND "HYPOSULPHITES."—A number of sulphites and "hyposulphites" are used in medicine because of a virtue which they are considered to derive, in common, from their acid radicals, and accordingly such salts form a distinct group of medicines, which it is convenient to discuss under a single heading. The class characteristics are as follows: The salts are soluble in water, have a combined saline and sulphurous flavor, and are, in physiological operation, locally bland and constitutionally innocuous. From a medicinal point of view, their most important reaction is that in the presence of stronger acids they are decomposed, with the evolution of sulphurous acid. Given medicinally, they are thought to undergo this change in the stomach through the agency of the free acid of the gastric juice. The decomposition is said to be slower with "hyposulphites" than with sulphites. As a secondary result of the chemical change, sulphates are formed, such being the combination in which the base reappears in the urine when a sulphite or "hyposulphite" is swallowed in ordinary dosage. Medicinally, these salts are employed with the single view of obtaining by their means the germicide and antiseptic action of sulphurous acid. But in this connection it must carefully be borne in mind that sulphites and "hyposulphites," while maintaining their chemical composition as such, have been proved experimentally to be practically devoid of either germicide or antiseptic power.[1] They can, therefore, even theoretically, be of avail in this line only under circumstances determining their decomposition and the evolution thereby of sulphurous acid. Such reaction may take place in the stomach, but is seemingly impossible in the blood, and with the inference naturally following from these premises clinical experience is in accord. For these salts have been vaunted in the treatment of pyrosis and sarcinæ, and their employment has proved fairly efficacious; but they have been even more strenuously advocated for the treatment of constitutional diseases assumed to be caused by infection of living organisms (Polli), and have, in the hands of the majority of the profession at least, signally failed. The salts have also been used, with variously reported success, as lotions for the cure of parasitic skin disease, or for the abatement of the pain of chilblains, sprains, etc.—applications in which it is certainly doubtful if they exert any specific influence.

II. THE SULPHITES AND "HYPOSULPHITES" USED IN MEDICINE.—The salts of this category are the normal and acid sulphite, respectively, of *sodium*, and the normal thiosulphate of *sodium* (commonly called *hyposulphite*).

Normal Sodium Sulphite, $Na_2SO_3.7H_2O$.—The salt is official in the United States Pharmacopœia as *Sodii Sulphis*, Sodium Sulphite. It occurs in colorless, transparent, monoclinic prisms, which effloresce in dry air. It is odorless, with a cooling, salty, and sulphurous taste. It dissolves in 4 parts of cold water and in 0.9 part of boiling water. It is sparingly soluble, only, in alcohol. The salt should be kept in well-stoppered bottles in a cool place.

Sodium sulphite may be used locally in twelve-per-cent. aqueous solution, and may be given internally in doses ranging from 1 to 4 gm. (gr. xv. to gr. lx.) three or four times a day.

Acid Sodium Sulphite, $NaHSO_3$.—The salt is official in the United States Pharmacopœia as *Sodii Bisulphis*, Sodium Bisulphite. It occurs in opaque, prismatic crystals, or a crystalline or granular powder, and on exposure to air slowly oxidizes and becomes the sulphate. The salt has an odor of sulphur dioxide and a disagreeable, sulphurous taste. It dissolves in 4 parts of cold water and in 2 parts of boiling water, in 72 parts of cold alcohol, and in 49 parts of boiling alcohol. It should be kept in small vials, well-stoppered and well-filled.

This sulphite is less stable than the normal sodium salt, and more disagreeable to taste. In other respects it is similar.

Normal Sodium Thiosulphate ("Hyposulphite"), $Na_2S_2O_3.5H_2O$.—The salt is official in the United States Pharmacopœia under its former chemical title of *Sodii Hyposulphis*, Sodium Hyposulphite. The present confusion in the use of the term *hyposulphite* arises from the fact that before the discovery by Schützenberger of what is now, and properly, called hyposulphurous acid—namely, the body H_2SO_2—the name in question was applied to thiosulphuric acid ($H_2S_2O_3$). Hence it comes about that though a true sodium hyposulphite is known, the salt that passes current by that name is not a hyposulphite, but a thiosulphate. The old title, however, is so firmly fixed by long and popular usage that it has been retained by the United States Pharmacopœia, and is the title by which the salt is universally known as a medicine. Sodium "hyposulphite" occurs as large, colorless, transparent, monoclinic prisms, or plates, which effloresce in dry air of a higher temperature than 33° C. (91.4° F.). It is odorless, with a cooling bitter, and somewhat sulphurous taste. It dissolves in 0.65 part of cold water and in about 0.5 part of water at temperature 20° C. (68° F.). In boiling water it decomposes rapidly. It is insoluble in alcohol. It should be kept in well stoppered bottles.

Sodium "hyposulphite" is more stable than the sulphites, undergoing decomposition by acids less easily. In properties, uses, and modes of administration it resembles sodium sulphite. The internal dose is generally from 1 to 1.30 gm. (gr. xv. to gr. xx.).

Besides the foregoing, potassium sulphite and magnesium sulphite have been used in medicine, but are out of vogue and not now official in the United States Pharmacopœia. They are, medicinally, duplicates of the sodium salts. *Edward Curtis.*

[1] Sternberg: American Journal of the Medical Sciences, April, 1883, p. 321.

SULPHOCARBOLATES—*Phenolsulphonates.*—Carbolic acid (*phenol*), added to strong sulphuric acid, dissolves with the formation of the acid body, $C_6H_4(OH).SO_3H$, termed *phenolsulphonic acid* by the chemist, but commonly known as *sulphocarbolic acid*. Sulphocarbolic acid unites with bases to the formation of salts, and in these salts it was hoped there might be found substances which would retain the therapeutic powers of carbolic acid while free from the poisonous properties of that body. So far as observation has gone, however, this hope does not seem to have been realized. A single salt of sulphocarbolic acid is official in the United States Pharmacopœia, as follows:

SODII SULPHOCARBOLAS, *Sodium Sulphocarbolate*, $NaSO_3C_6H_4(OH)$.—This salt occurs in colorless, transparent, rhombic prisms, which effloresce somewhat in dry air. It is odorless, with a cooling, saline, and bitterish taste. It dissolves in 4.8 parts of cold water, and readily in boiling water. It dissolves in 132 parts of cold alcohol and in 10 parts of boiling alcohol.

Sodium sulphocarbolate is a bland salt, producing but little constitutional disturbance in ordinary medicinal doses beyond some lightness of the head. It has been prescribed in doses ranging from 0.65 to 2 gm. (from gr. x. to xxx.) for the purpose of constitutional antisepsis in so called zymotic diseases, but without striking results. *Edward Curtis.*

SULPHOCYANIDES (*Rhodanides, Thiocyanates*).—The sulphocyanides, or salts of sulphocyanic acid (CNSH), are of interest in medical science chiefly from the fact of their occurrence in certain of the secretions and excretions of the animal body. Even before the discovery of sulphocyanic acid, Treviranus noted the red coloration which results when human saliva is mixed with a solution of ferric chloride; but Tiedemann and Gmelin first correctly attributed the reaction to the presence of a sulphocyanide. Their experiments further indicated the possibility of finding sulphocyanide in the urine, in which its normal occurrence was subsequently investigated by Gscheidlen, Külz, I. Munk, and Bruylants.

The observations of F. Krüger have demonstrated, in contrast to those of some earlier investigators, that sulphocyanides are almost constantly present in the saliva of man, although the quantity involved is subject to considerable variation. With this the experience of Schneider and of the writer fully agrees. The latter found an average sulphocyanide content of 0.007 per cent. (as KSCN) in mixed human saliva. Notable is the fact that the content of sulphocyanide is decidedly higher in the case of smokers, contrasted with non-smokers, while it is independent of age, sex, or the state of preservation of the teeth. Claude Bernard was the first to call attention to the pronounced difference just referred to, but he failed to appreciate the true cause in attributing it to the presence of nicotin from the tobacco. A post-secretory formation of sulphocyanide in saliva has also failed of proof. The following data, collected under the writer's direction from observations on two hundred and twenty-nine individuals, give an indication of the average difference between the saliva of smokers and that of non-smokers:

SULPHOCYANIDE REACTION IN HUMAN SALIVA (Schneider).

	Smokers, per cent.	Non-smokers, per cent.
Traces (less than 0.0016 per cent.) in....	1	23
Weak reaction (0.0016-0.008 per cent.) in	23	72
Strong reaction (more than 0.008 per cent.) in..............................	76	5

Our observations completely confirm those of Krüger, who found 0.0117 per cent. of KSCN in the combined saliva of a number of smokers, and only 0.0041 per cent. in the secretion of an equal number of non-smokers. No quantitative variations from these results were obtained with saliva from women and children. The excretion of sulphocyanide may be considerably diminished by prolonged stimulation of the salivary glands. For example, in one case when the flow of saliva was continuously provoked by chewing a piece of soft paraffin for three hours, it diminished as follows: At 8:15 o'clock the saliva contained approximately 0.004 per cent. (KSCN); at 10 o'clock, approximately 0.003 per cent. (KSCN); at 11 o'clock, approximately 0.002 per cent. (KSCN); at 12 o'clock, approximately 0.002 per cent. (KSCN). No constant relationship between the content of sulphocyanide and the composition of the saliva has been ascertained.

The parotid saliva of man has uniformly been found to be richer in sulphocyanide than the submaxillary saliva collected from the same individual at the same time. The two corresponding glands (right and left) usually afford reactions of like intensity. The difference between smokers and non-smokers is found to hold good for the individual glands also, as the following data from Schneider indicate:

Comparison of the Sulphocyanide Reaction of the Parotid and Submaxillary Salivas.

HSCN reaction.	Smokers.		Non-smokers.	
	Parotid saliva.	Submaxillary saliva.	Parotid saliva.	Submaxillary saliva.
Trace	None.	4	2	19
Weak	4	13	22	5
Strong	24	11	None.	None.

Regarding the origin of sulphocyanides in the organism little is known. Since they contain Nitrogen and Sulphur, they have been assumed to arise from the metabolism of proteids. Various attempts have been made to establish some clinical significance for the variations in the sulphocyanide output (Fenwick, Grober, Muck). Thus Grober states that of one hundred patients in the Jena medical clinic, sixty who yielded weaker sulphocyanide reactions in their saliva were more ill in general than the remaining forty with whom stronger reactions were obtained. He concluded from these observations that the excretion of KSCN is presumably dependent upon the extent to which proteid utilization and katabolism proceed in the organism; that, since these processes are diminished in cachectic patients with severe chronic illness, the excretion of sulphocyanide which is derived ultimately from proteids must be slight or wanting. An exhaustive systematic study of this subject is necessary before any deductions of importance can be made.

According to Ellenberger and Hofmeister, sulphocyanides are missing in the saliva of the horse, ox, sheep, goat, and pig. Whether they occur in the saliva of the dog is doubtful (Munk). Nencki has succeeded in isolating sulphocyanic acid from the gastric juice (obtained free from contamination with saliva) from the dog and cat. The quantity was estimated at 5 mgm. per litre. In the pancreatic juice, muscle, and liver of the dog none could be detected. With blood positive results have been obtained (Nencki, Gscheidlen, Bruylants). Wróblewski has shown that sulphocyanic acid retards the action of pepsin and rennin in artificial digestions.

Sulphocyanides have been detected in the urine of the dog, cat, rabbit, horse, and cow. The quantity found in human urine is given by various investigators at 0.003–0.035 gm. per litre, thus yielding about one-third of the so-called "neutral" sulphur of the urine. According to Bruylants, sulphocyanide occurs only in the urine of those species which excrete their Nitrogen in the form of urea; in birds and reptiles it is wanting.

In cow's milk Musso has estimated a minimum of 0.0021 and a maximum of 0.0046 sulphocyanide (as NaSCN) per litre. Whether the compound arises within the cells of the mammary gland, or is merely secreted directly from the blood as a preformed product, is left undecided.

Muck has demonstrated the presence of sulphocyanide in the fluid which bathes the conjunctiva, as well as in the secretion from the nasal mucosa. He obtained the reaction in individuals with catarrhal as well as healthy membranes, and observed that its intensity varied with that of the saliva.

The antiseptic value attributed to the sulphocyanide in the saliva has no experimental justification. Even relatively strong solutions possess little bactericidal power (Nicolas and Dubief, Treupel and Edinger). Sodium sulphocyanide has been administered to rabbits for months without producing unfavorable symptoms, thus contrasting with the corresponding toxic cyanide. Cyanogen compounds may be transformed in the body into sulphocyanides, the latter being a synthetic product formed from the ingested cyanogen radical and the SH group of decomposed proteid (Lang). The reaction is a purely chemical one, apparently not dependent on the living tissue (Pascheles). Administration of a thiosulphate (or sulphide) may greatly diminish the toxicity of a cyanide, owing to the formation of the comparatively harmless sulphocyanide, thus:

$$NaCN + SO_2\begin{smallmatrix}\diagup SNa \\ \diagdown ONa\end{smallmatrix} + O = NaSCN + Na_2SO_4.$$

On the basis of this theory the intravenous injection of sodium sulphide has been advised in poisoning with prussic acid and cyanides; and animals seem to survive an otherwise lethal dose when this is done.

Sulphocyanides introduced directly into the organism are excreted again unchanged. The path of excretion lies through the kidneys, and several days usually intervene until the salt is completely eliminated. This is well shown in the experiments of Pollak, from which the following table is constructed:

Excretion of Sulphocyanides.

Animal.	Substance introduced.	Quantity eliminated in urine.	Duration of elimination.
Dog, 6,350 gm.	1.268 gm. NaCNS subcutan.	1.189 gm.	Four days.
Dog, 6,350 gm.	1.440 gm. NaCNS subcutan.	1.482 gm.	Four days.
Dog, 8,970 gm.	.907 gm. NaCNS subcutan.	.904 gm.	Five days.
Dog, 8,970 gm.	1.012 gm. NaCNS per os....	1.038 gm.	Five days.
Dog, 7,800 gm.	.510 gm. $(NH_4)CNS$ subcutan.	.49 gm.	Five days.
Rabbit 1,420 gm.	.220 gm. NaCNS subcutan.	.206 gm.	Nine days.
Man	2.200 gm. NaCNS per os....	2.167 gm.	Six days.

Of the various tests which have been proposed for the detection of sulphocyanides in animal fluids, the *ferric chloride reaction* is most commonly used. Thus if a few cubic centimetres of saliva are slightly acidified with hydrochloric acid and then treated with a very dilute solution of ferric chloride, a red color develops in the presence of the sulphocyanide. Occasionally it is necessary to concentrate the saliva before trying the reaction. Gscheidlen recommended the use of filter paper which has been dipped in a very dilute acidified solution of ferric chloride and allowed to dry. The amber-colored test paper takes on a reddish stain when a drop of saliva is applied to it. Solera suggested the use of *iodic acid* in the presence of starch paste. Iodine is liberated by the sulphocyanide and reacts with the starch to form the characteristic blue compound. This reaction is exceedingly delicate. Krüger has introduced the use of test papers prepared as follows: Filter paper of good quality is saturated with a half-per-cent. starch paste containing a little pure iodic acid in solution, and is then dried in the air. When carefully prepared, this test paper responds readily to very small quantities of sulphocyanide by giving a blue coloration due to the liberation of iodine; and with proper precautions the reagent papers can be preserved without decomposition for a considerable time.

In testing for, or estimating sulphocyanides in the urine, special precautions are necessary; and these must be ascertained from appropriate handbooks, such as Huppert's "Analyse des Harns." The quantitative determination of sulphocyanic acid in the saliva may be carried out by Munk's method:

A known weight of saliva is evaporated to dryness, and an alcoholic solution of the dry residue is made; this is evaporated to dryness, dissolved in water, and the clear solution is precipitated by means of silver nitrate and nitric acid; the precipitate is washed, collected on a filter, and dried at 100° C.; it is then ignited in a silver dish, with pure sodium hydrate and potassium nitrate. The fusion products are dissolved in water, and the solution is treated with hydrochloric acid and barium chloride, to precipitate the sulphuric acid formed by the oxidation of the sulphocyanic acid. From the weight of the barium sulphate precipitate the amount of sulphur originally present in the sulphocyanide is then calculated.

SULPHONAL.—(*Dimethyl-methane-diethyl-sulphone*) $(CH_3)_2C(SO_2C_2H_5)_2$. Sulphonal was not placed in the Pharmacopœia on account of its being a proprietary article. It is official in the British Pharmacopœia as "a product of the oxidation of mercaptol, obtained by the oxidation of acetone and mercaptan." It forms in colorless, odorless, and nearly tasteless prismatic crystals; soluble in 450 parts of cold water and 15 parts of boiling water. It is soluble in 50 parts of alcohol.

Professor Kast introduced it in 1888 as an hypnotic, and it has proved so efficacious that it is now recognized as one of the best drugs we possess for that purpose. It is purely a soporific, and is rarely employed for any other purpose than to procure sleep. It does not influence the body temperature, it has no antiseptic qualities, and as an analgesic is of no practical value. Unlike other narcotics, it has no period of excitement, does not check or alter the secretions or derange the digestive organs, and is almost without any influence upon the heart or circulation. Devoid of these many disadvantages, its success as an hypnotic is readily understood.

The action of sulphonal is directed to the central nervous system as a sedative, inducing a quiet and calm sleep from which the patient awakens refreshed. In the case of animals, when excessive doses are given the sleep deepens into coma, convulsions, and paralysis. Its sedative action extends to the spinal cord, lessening reflex action. In animals the loss of power in the hind limbs may be an early symptom. After absorption sulphonal is decomposed in the system and excreted in the urine in the form of sulphur compounds. Some observers have reported the presence of pure sulphonal in the urine after its free administration. At times sulphonal proves irritating to the kidney, causing lessened secretion and pain. It may also give rise to a peculiar reddish-brown discoloration due to the presence of *hæmatoporphyrine*, which may terminate in death (*British Medical Journal*, 1901, i., p. 1473).

Sulphonal has proved of greatest service where the insomnia is of purely nervous origin, as in neurasthenia, mental depression, overwork, and worry, and has found a field of great usefulness in the various forms of mental disease. When pain is the cause of the sleeplessness, its good effects are greatly modified, but in many forms of neuralgia and pain of a reflex character it may be used with success. Where pain is due to organic disease it has no influence whatever. In the insomnia of acute and chronic disease, and during convalescence from disease, it is of much benefit, but requires to be given with some caution, particularly when there is much debility or prostration, and in the aged. In the sleeplessness of cardiac disease and of other forms of organic or mechanical derangement, it is not of much use. In delirium tremens it has been much used, in many instances with benefit, but in these cases the effect is uncertain, and the dose required is excessive and approaching the limit of its physiological action.

As an hypnotic, the dose is from fifteen to thirty grains. It is usual to commence with fifteen grains and increase the quantity until the proper effect is produced. Ten grains will often be sufficient in the aged and debilitated, or where the insomnia is of a mild degree. Under ordinary conditions thirty grains is a perfectly safe dose, and this quantity is usually required to produce its full hypnotic action. On account of its insolubility the action is slow, and the dose should be administered at least one hour before bedtime in hot solution. Six or eight ounces of boiling water are recommended to dissolve thirty grains. Hot milk and broth may also be made use of; tea and coffee are frequently used, but they undoubtedly, to a certain extent, counteract its effect. It may also be administered in alcohol or any spirituous liquor.

The sedative action of sulphonal on the spinal cord and nerve centres has led to its use in some nervous troubles. In chorea it has been given to children in doses of from two to five grains, and has been followed by a fair percentage of successes. In old-standing cases it has little or no influence.

It is now fully recognized that sulphonal is not without its toxic action, and numerous fatal cases have followed its employment. The simplest symptoms that may arise include drowsiness and stupor, giddiness, vertigo, ataxia of the tongue and muscles of the throat and face, and of the extremities. These symptoms gradually disappear after an interval of from ten to twelve hours, without leaving any ill effects. The more severe symptoms are profound coma, muscular twitchings, paralysis of sphincters, hallucinations, delirium, anuria, great prostration.

An erythematous patch is often produced, accompanied by itchiness and pain. The symptoms of toxic action generally appear after large doses, or after repeating an ordinary dose of thirty grains several times. In some instances, when the patient is debilitated and the subject of some wasting disease, very small doses may be followed by toxic symptoms. It has been remarked that poisonous symptoms are much more frequent in females.

The fatal cases that have been reported were due to overdoses or to the prolonged use of the drug.

In one case (*British Med. Journal*, October 25th, 1890) the patient was supposed to have taken about an ounce of sulphonal. The stupor which followed deepened into insensibility and anæsthesia, the pupils remaining normal and acting to light, while the conjunctiva was insensitive. Breathing was natural, pulse very slightly disturbed, but the temperature ranged between 100 and 103° F. A profuse perspiration bathed the body, and there was total suppression of urine after the first day. On the third day the breathing suddenly became short and jerky and ceased altogether. Another case is reported (*Medical News*, August 10th, 1890) in which two doses of fifteen grains, given within an hour and a quarter of each other, caused death. The patient was a young insane woman who had formerly been given large quantities of chloral and other hypnotics. No medicine had been given on the day she took the sulphonal. She slept quietly all night, and on the following day was drowsy, but could be roused and made to talk rationally; sleep at once came on when she was left alone. The pulse and respiration were slightly accelerated and the pupils normal. Eighteen hours after taking the medicine the pupils began to contract and her temperature rose to 102° F.; in forty hours cyanosis began, and she died from failure of respiration.

Lépine (*La Semaine médicale*, January 20th, 1893) has collected a series of thirteen cases terminating in death. These patients had taken the drug for periods varying from sixty to over a hundred days in ordinary doses. Severe symptoms suddenly supervened, which would indicate a cumulative action, and death followed within a few days, although the medicine was stopped at once. In some instances very large doses have been taken without causing death; in one case four hundred and sixty-three grains were recovered from after one hundred and fourteen hours' sleep (London *Lancet*, 1889, i., 915). See also *Synthetic Products, Poisoning by*.

Beaumont Small.

SULPHO-PARALDEHYDE, tri-thialdehyde $(C_2H_4S_2)_3$, occurs in crystals, is soluble in alcohol and insoluble in water, and is used in dose of 1–4 gm. (gr. xv.–ʒ i.) as a hypnotic.

W. A. Bastedo.

SULPHO-SALINE SPRING.—Hamilton County, Ohio.
POST-OFFICE.—Cincinnati.

ACCESS.—By Elm Street cars to Henry Street, thence one block west.

This well is 2,408 feet in depth and flows in an abundant and continuous stream at a temperature of 62° F. An analysis by Professor Wayne, of Cincinnati, shows the following ingredients: One United States gallon contains (solids): Magnesium carbonate, gr. 9.13; calcium carbonate, gr. 19.34; calcium sulphate, gr. 29.20; potassium sulphate, gr. 2.30; sodium phosphate, gr. 1.34; sodium chloride, gr. 534.77; magnesium chloride, gr. 17.27; calcium chloride, gr. 22.19; potassium chloride, gr. 3.95; magnesium bromide, gr. 0.39; magnesium iodide, gr. 0.30; iron oxide, gr. 0.43; silica, gr. 0.79; loss, gr. 0.76. Total, 642.16 grains. This analysis shows the presence in considerable amounts of valuable ingredients. The water is well adapted for the treatment of portal congestion, hemorrhoids, metallic poisoning, etc. In the form of baths it is useful in many of the chronic skin affections and in advanced syphilis. A very elegant and elaborate bath-house has been fitted up and supplied with all the modern appurtenances of such an establishment.

James K. Crook.

SULPHUR.—Sulphur is used in medicine in the condition of fine powder, three styles of which are official in the United States Pharmacopœia, as follows:

SULPHUR SUBLIMATUM, *Sublimed Sulphur*.—This preparation, commonly called *flowers of sulphur*, is crude sulphur purified by distillation in an apparatus so arranged that the vaporized sulphur shall condense in the form of a powder upon the walls of the receiving chamber. Sublimed sulphur is a fine, citron-yellow powder, of a slight, characteristic odor, and generally of a faintly acid taste and an acid reaction. It is insoluble in water or alcohol. When ignited, it burns with a blue flame, forming sulphur dioxide gas. Sublimed sulphur always contains a little sulphuric acid, whereby it is unfitted for internal medicinal use.

Sulphur Lotum, Washed Sulphur.—This preparation is simply sublimed sulphur freed from contaminating sulphuric acid. The sulphur is digested for three days with diluted ammonia water, by which process the sulphuric acid is fixed as ammonium sulphate, and the mass is then thoroughly washed with water upon a muslin strainer. The ammonium sulphate is thus washed away, and the purified sulphur is finally dried at a gentle heat, and passed through a No. 30 sieve. Washed sulphur is a fine, citron-yellow powder, odorless and almost tasteless, insoluble in water or alcohol. When derived from a sulphur originally obtained from metallic sulphides, washed sulphur may contain the very dangerously contaminating substance, arsenic, in the form of the trioxide or trisulphide of that element. Proof of absence of arsenic is afforded by digesting a sample of washed sulphur with two parts of ammonia, filtering, and finding the filtrate unaffected by supersaturation with hydrochloric acid, and not precipitated by passing through it a stream of hydrogen sulphide.

SULPHUR PRECIPITATUM, *Precipitated Sulphur*.—This preparation, formerly known as *milk of sulphur*, is an exceedingly fine powder of sulphur, gotten by precipitating with diluted hydrochloric acid a solution of sulphur salts of calcium, obtained by mixing sublimed sulphur and slaked lime with water. The sulphur, after precipitation, is collected upon a strainer, thoroughly washed with water, and dried at a gentle heat. Precipitated sulphur is a very fine, yellowish-white, amorphous powder, odorless and almost tasteless, insoluble in water or in alcohol. Precipitated sulphur should stand the same tests for absence of free acid and of contaminating arsenic as washed sulphur (see above). This variety of sulphur powder differs from the foregoing in being lighter in color and of finer particles. From the latter fact it derives the advantages of greater smoothness and readiness of mixing with fluids; but, to offset, it has the disadvantage of tending to develop an acid upon keeping.

Sulphur is insoluble in water and practically so in alcohol, but dissolves in varying proportions in solutions of the alkalies and in oils, fixed and volatile. Because of its insolubility in aqueous fluids, sulphur is practically devoid of physiological activity while under its own form, but, when rubbed in ointment upon the skin or when taken internally, a feebly irritant action appears, presumably due to a sulphide formed in small quantity by the chemicals present in the secretions of the part. What little of an internally taken dose of sulphur is absorbed is also probably in the condition of a sulphide, and the constitutional effects that follow are a feeble reflex of those of the alkaline sulphides (see *Sulphides*). In single, considerable dose the local irritation displayed by sulphur determines increased intestinal activity, showing itself by relaxation of the bowels, but this with but little increase of secretion. The stools are therefore generally composed of solid or semisolid fecal matter, and the operation of the medicine is mild and slow, the call to stool rarely occurring until from six to eight hours after the taking of the sulphur. If habitually used as a laxative, sulphur may induce a low catarrh of the alimentary tract. A disagreeable feature of its internal taking for any purpose is the tendency to the generation of flatus, offensive from the presence of sulphureted gases.

The therapeutic applications of sulphur are as follows: By some it is given internally as a means of getting the constitutional effects of the sulphides in constitutional diseases, but by the majority of practitioners the internal use is in laxative dose only, for a laxative effect. Such dose is from 4 to 12 gm. (ʒ i.–iij.), the washed or precipitated preparations being selected, and the powder mixed with molasses or diffused in milk for the taking. Externally, ointments containing sulphur are a good deal used as mildly irritant applications in skin diseases generally, and, specifically, as efficient parasiticidal dressings in itch. The following ointment is official in the United States Pharmacopœia:

Unguentum Sulphuris, Sulphur Ointment.—This preparation is compounded of thirty parts of sublimed sulphur and seventy of benzoinated lard, thoroughly incorporated. It may be applied without dilution, and is a very commonly used ointment for the treatment of the itch. It has a disagreeable sulphuretted smell, which may to a certain degree be masked by the addition of a little of some odoriferous volatile oil. *Edward Curtis.*

SULPHUR DIOXIDE (formula SO_2).—This compound, commonly miscalled *sulphurous acid gas*, is the product of the combustion of sulphur in air. It is a colorless gas, of a well-known characteristic "sulphurous" odor, and is both offensive to the nostrils and intensely irritant to the larynx. Even the fumes of a single burning sulphur match-head easily excite coughing, and air highly charged with the gas is fatal to life. Sulphur dioxide dissolves freely in water—in one-fiftieth of its volume at ordinary temperatures—forming in the process of solution an acid body, *sulphurous acid* proper (H_2SO_3) (see *Sulphurous Acid*).

The medicinally valuable property of sulphur dioxide is its peculiar noxiousness to the vitality of disease germs—a germicidal potency in which this compound, among gases, is rivalled only by formaldehyde, chlorine, and the vapors, respectively, of bromine and of iodine. Yet in its application to disinfect apartments the inherent uncertainties in the general method of aërial disinfection must never be forgotten. Could we be certain that every disease germ present in a chamber would be fully exposed to the action of the disinfectant gas, then we might rely with corresponding fulness upon the disinfection thus attained; but when we bethink us how easily these germs, microscopic in size, may safely be fortified against assaults of a gas by lodgment in cracks and crannies of furniture and fabrics, then we cannot but realize the important truth that even the most thorough aërial disinfection is at best but an unreliable procedure. In this connection the strong and offensive smell of sulphur dioxide is a distinct advantage, since, after fumigation by the gas, a chamber and all articles therein must be thoroughly aired, and thus additionally disinfected before the human nose will permit of their resumed use.

For the determination of the exact germicidal power of sulphur dioxide, very careful experiments were made by Sternberg,[1] by submitting vaccine virus, moistened with glycerin on the one hand, and dried upon ivory points upon the other, to the action, in a closed chamber, of air charged with varying percentages of sulphur dioxide, the exposure ranging from six to twelve hours. After exposure the virus, or the charged ivory points, were used for vaccination side by side with some of the same sample of virus which had not been exposed to the germicide. The general results were that in the case of moist lymph, destruction of infective power followed a twelve-hour exposure to air charged with a proportion of sulphur dioxide such as would be produced by burning three-quarters of a grain of sulphur for each cubic foot of air; and, in the case of the dried virus, similar results followed with an impregnation equivalent to the combustion, per cubic foot of air, of three grains of sulphur. These results accord with common experience, and teach that at least a one-per-cent. impregnation of air with sulphur dioxide will ordinarily be required to sterilize floating germs.

For the practical application of sulphur dioxide as an aërial disinfectant, the gas is most easily and cheaply obtained by burning sulphur, and in calculating the quantity of sulphur required it is obviously wisest to err very far on the safe side. A good rule, therefore, is to allow from two to three pounds for each one thousand cubic feet of chamber to be disinfected. The strength of fumes thus generated being vastly in excess of what is respirable, the procedure is possible only in vacated rooms. In a chamber to be operated upon, therefore, all living creatures must be removed, and every possible outlet for the gas, such as doorways, windows, and chimneys, must be closed, and even cracks and keyholes should be stopped with cotton or pasted over with paper. Then all articles needing disinfection must be thoroughly exposed on all sides to free access of the gas—bureau-drawers being opened, carpets, curtains, and blankets hung over lines across the room, and mattresses ripped open and the hair loosely strewn on the floor. The proper quantity of sulphur, in the form of sublimed sulphur, is then best mixed with one-fortieth of its weight of powdered charcoal, to secure readier combustion, and put into an iron pot, or upon a metal plate resting upon the legs of a half-open pair of tongs set across a wash-tub half full of water. By these precautions all danger of accidental setting of the floor on fire is avoided. A single door being left unsealed, the operator fires the sulphur by a live coal or a teaspoonful of flaming alcohol, and immediately retires, closing and sealing the door behind him. The sulphur is left to burn itself out, and next day the chamber is cautiously entered, the windows are thrown open, and all articles thoroughly aired. It is possible also to generate sulphur dioxide by burning carbon disulphide in a specially constructed lamp, but from the great inflammability of that compound the procedure is not altogether safe, and presents no advantages over the simple method by the combustion of sulphur. A convenient way of burning the sulphur is by use of sulphur candles, so called, in which a wick is incorporated in a moulded mass of sulphur. By lighting the wick sulphur dioxide is generated.

The use of sulphur dioxide as an aërial disinfectant is now largely superseded by the similar use of formaldehyde. *Edward Curtis.*

[1] American Journal of the Medical Sciences, April, 1883.

SULPHUR IODIDE.—Under the title *Sulphuris Iodidum*, Sulphur Iodide, the United States Pharmacopœia recognizes a preparation made by fusing by heat a mixture of one part of washed sulphur and four parts of iodine. The fused mass, after cooling, is broken into pieces and kept in glass-stoppered bottles. These lumps are grayish-black in color and have a metallic lustre. They have the odor of iodine and an acrid taste. The substance is practically insoluble in water, but dissolves in about sixty parts of glycerin. Alcohol and ether dissolve out the iodine and leave the sulphur. On exposure to the air, also, iodine is gradually lost.

This substance is differently regarded by chemists, some considering it a definite compound, corresponding to the formula I_2S_2, and others thinking it more probably a mere physical mixture. If a true chemical compound, it is one of exceptional instability, as the foregoing narration of its properties makes evident. To the therapeutist it presents itself practically as a joint representative of free sulphur and free iodine. It has occasionally been given internally for the purposes for which iodine is so administered, but the commoner employment is external as a gently irritant, iodized application in various skin diseases. It is best applied in the form of ointment made with lard, containing the sulphur iodide in the proportion of about eight per cent.

Edward Curtis.

SULPHURIC ACID.—Oil of Vitriol, H_2SO_4. This well-known acid is official in the United States Pharmacopœia under the title *Acidum Sulphuricum*, Sulphuric Acid, and is defined to be "a liquid, composed of not less than 92.5 per cent. of absolute sulphuric acid, and not more than 7.5 per cent. of water" (U. S. P.). Sulphuric acid is a heavy liquid of an oily appearance, colorless when newly made, but apt to acquire a smoky hue upon keeping. The specific gravity varies in different samples, but a gravity of 1.835 is recognized as standard by the United States Pharmacopœia. The acid has an intense affinity for water. Mixed with that fluid, it unites therewith with the evolution of considerable heat and with a contraction of volume, forming a clear solution. By reason of the same affinity, many organic bodies are decomposed upon treatment with sulphuric acid, the acid abstracting from their molecule the elements of water. Thus, by dehydration, oxalic acid is chemically broken up, alcohol is converted into ethylene gas (C_2H_4), wood and sugar are blackened, and textile fabrics and animal tissues are destroyed. Sulphuric acid, if diluted, also attacks most of the common metals, the prominent exceptions being gold, platinum, and iridium. Certain of the metals, such as copper, mercury, antimony, bismuth, tin, lead, and silver, are also acted upon by the concentrated acid, if the same be heated.

Upon the living animal system strong sulphuric acid acts purely as a powerful caustic. Its action is a spreading one, and the sloughs have a dusky or blackish hue, quite different in color from the yellow sloughs produced by nitric or hydrochloric acid. Swallowed in any quantity, the strong acid is an intense corrosive poison.

Therapeutically, strong sulphuric acid is occasionally used as a caustic, but the very intensity of its action is in its disfavor, so that nitric acid is generally preferred. The acid must be kept in glass-stoppered bottles.

Diluted, so as not to be corrosive, sulphuric acid, like all sour acids, tends to check acid, and to increase alkaline secretions, to inhibit fermentations, and, of course, to neutralize alkalinity. Dilute preparations of sulphuric acid are, therefore, available to repress morbid sweatings, both applied locally as lotions, and given internally to allay thirst and quicken appetite; to prevent fermentation of food in the *primæ viæ*, and so to cure diarrhœas due to the irritation of the products of such fermentations, and to neutralize the alkali of alkaline pyrosis. For these various purposes the following official preparations of the United States Pharmacopœia are available:

Acidum Sulphuricum Dilutum, *Diluted Sulphuric Acid.*—This preparation is a simple aqueous dilution of sulphuric acid, of ten-per-cent. strength. It is a colorless fluid, intensely sour of taste, and of about the specific gravity 1.070. It should be kept in glass-stoppered bottles. This grade of acid, although not corrosive, is quite irritant, and, for medical use, requires considerable further dilution. The dose is from ten to thirty drops, diluted thirty- or fortyfold, and to be taken through a tube, with the mouth well rinsed after the swallowing.

Acidum Sulphuricum Aromaticum, *Aromatic Sulphuric Acid, Elixir of Vitriol.*—This preparation consists of alcohol charged with sulphuric acid and tincture of ginger, and flavored, in addition, with a trace of oil of cinnamon. It contains about twenty per cent., by weight, of sulphuric acid. The preparation is a limpid, yellow fluid of an aromatic, ethereal, and strongly sour taste, and of specific gravity about 0.939. As its odor suggests, it probably contains some ethereal product of a reaction between the acid and alcohol of its composition. The United States Pharmacopœia considers, thus, that there is a certain amount of ethyl-sulphuric acid present. Aromatic sulphuric acid should be kept in glass-stoppered bottles.

This preparation is the favorite one for the internal administration of sulphuric acid. It is to be given in the same manner as the dilute acid (see above), and in the same or somewhat lesser doses. *Edward Curtis.*

SULPHURIC ACID, POISONING BY. See *Acids, Mineral, Toxicology of.*

SULPHUROUS ACID.—H_2SO_3. Sulphur dioxide gas (SO_2) is readily absorbed by water, and in so dissolving is to be regarded as uniting with water, molecule for molecule, with the formation of the acid body, H_2SO_3. The United States Pharmacopœia recognizes under the official title *Acidum Sulphurosum*, Sulphurous Acid, an acid representing not less than 6.4 per cent., by weight, of sulphur dioxide, and of specific gravity not less than 1.035. Sulphurous acid is a colorless fluid, smelling pungently of sulphur dioxide, and tasting both sulphurous and sour. It has a strong acid reaction, and first reddens and then bleaches litmus paper. It is wholly volatilized by heat, and tends constantly to undergo conversion into sulphuric acid by the absorptions of oxygen. This change is hastened by the action of light, hence the Pharmacopœia directs that sulphurous acid be put up in glass-stoppered, dark amber-colored bottles, and be kept in a cool and dark place. The pharmacopœial process for making the acid is to generate sulphur dioxide by heating a mixture of sulphuric acid and charcoal, and to conduct the mixed sulphur and carbon dioxides into distilled water. The sulphur dioxide dissolves in the water with the formation of sulphurous acid, and the carbon dioxide mostly escapes.

In its medicinal properties sulphurous acid resembles sulphur dioxide (see *Sulphur Dioxide*), and may practically be regarded, indeed, as a simple aqueous solution of that compound. It is a pretty potent germicide, and upon tender surfaces of the animal body is decidedly irritant. It bleaches vegetable colors. The acid is used, externally, as a wash in parasitic skin diseases, generally diluted two- or threefold, and, internally, is occasionally prescribed in cases of pyrosis and sarcinæ. It is, however, an exceedingly disagreeable medicine to take. The dose is 4 gm. (about one fluidrachm) of the official acid, taken in a wineglassful of water. *Edward Curtis.*

SUMACH or **SUMAC.**—Smooth Sumac. (*Rhus glabra*, U. S. P.) The dried ripe fruit of *Rhus glabra* L. (fam. *Anacardiaceæ*). This very handsome shrub or small tree grows abundantly in dry places throughout the greater part of North America. It is well distinguished by its smooth young branches from the stag-horn sumac (*R. typhina* L.) upon which they are velvety, and it bears little resemblance to other species. R. copallina has the leaf rachis winged between the leaflets. The poison sumac (*R. vernix* L.; see *Poisonous Plants*) has smooth green or yellowish-green fruits, in very loose open panicles, while that of *R. glabra* occurs in very large and very dense pyramidal masses. The commercial fruits are about a sixth of an inch long and broad, and somewhat flattened, ovoid, obtuse, truncate at the base. The epicarp is of a deep crimson color and glandular-tomentose, and contains a single smooth yellowish stone. The hairy covering is strongly acid and astringent. The hairs are rather short and matted, those of the stag-horn sumac being shaggy. The drug contains two different classes of constituents, imparting distinct medicinal properties, besides the fatty oil of the seeds. About two per cent. or three per cent. of tannic acid and a very little gallic acid make it a mild and useful astringent, while its malic acid renders it distinctly refrigerant. For the latter purpose it is now scarcely employed, although it was largely so during earlier periods, when lemons and similar refrigerant fruits were less readily obtainable in country districts. As an astringent, sumac berries are usually employed for gargling, in various forms of sore throat, and are frequently combined with chlorate of potash. The acid taste renders this more grateful than other throat astringents. The drug is also often used as an intestinal astringent. The official preparation is the fluid extract, which contains ten per cent. of glycerin, and the internal dose of which is 2 to 4 c.c. (fl. ʒ ss.–i.). This is commonly diluted with from one to three parts of water, to be used as a gargle, though the decoction and infusion are more commonly employed for that purpose.

Henry H. Rusby.

SUMBUL.—U. S. P. (*Sumbul Radix*, B. P., *Muskroot*.) The dried root of *Ferula Sumbul* Hook., f. (fam. *Umbelliferæ*). This large perennial herb, belonging to the asafœtida-, galbanum-, and ammoniacum-yielding group of the family, and inhabiting the same general region, has a large, rather short cylindrical root, attaining a diameter of four or five inches, and a length of say a foot, when it divides into several stout branches. The root itself as a perfume, and afterward as a medicine, appeared in Europe about 1840.

Sumbul occurs in transverse segments, varying in diameter from about 2 to 7 cm., and in length from 15 to 30 mm.; light, spongy, annulate or longitudinally wrinkled; bark thin, brown, more or less bristly fibrous; the interior whitish, with numerous brownish-yellow resin dots and irregular, easily separated fibres; odor strong, musk-like; taste bitter and balsamic.

CONSTITUENTS.—The most important constituent is the *resin*, of which there is nine per cent. (Flückiger); it has a musky smell, more developed in contact with water, and a bitter, aromatic taste. The root contains also a small quantity of dull-bluish-colored oil.

ACTION AND USE.—Sumbul has not any important medicinal value; like asafœtida, and its namesake, musk, it is gently stimulant and slightly antispasmodic, and may be given for the same nervous conditions as they; but its principal employment is in the preparation of some perfumes, where it takes the place of musk. A tincture (*Tinctura Sumbul*, strength one-tenth) is official.

W. P. Bolles.

SUMMERVILLE, SOUTH CAROLINA.—This popular winter resort, among the pines, is situated in the southeastern portion of the State, twenty two miles northwest from Charleston. Its favorable features as a health resort are its dry sandy soil, pine forests, equable mild temperature, and freedom from the enervating heat peculiar to points farther south. The pines are an especial feature of the place, and abound not only about the town but are thickly scattered throughout it "in the middle of the streets, on the sidewalks, in the gardens, and in fact everywhere." There are local laws prohibiting the cutting down of these trees. The atmosphere is permeated with their balsamic odor, and if there is any virtue in such a naturally medicated air it must surely be found here.

The population of the town is about 5,000 souls, and there are various churches, schools, shops, good markets, etc.

The sanitary condition is carefully supervised by an efficient board of health, of which Dr. A. H. Hayden is president, to whom the writer is indebted for climatic and other information contained in this article. Tuberculosis is included in the list of contagious or infectious diseases required to be reported to the board, and whenever in a hotel or any other building a case of consumption has "lived, resided or died," it must be reported in writing to the secretary of the board of health; and "immediately upon receipt of each report, the health officer shall, at the expense of the occupant or owner of the premises, cause said premises to be at once fumigated and properly disinfected." [Extract from the Rules and Regulations of the Board of Health.]

The natural drainage is excellent, and this is supplemented by an open canal, on one side of the town, some miles in length, and into this accessory canals or ditches empty. Soil carts are also employed by the town.

The water supply is very generally derived from open wells, although the Pine Forest Inn and Pinehurst (Tea Farm) have artesian wells.

The accommodations are good, there being several first-class hotels and many boarding-houses.

The outdoor attractions and amusements are walks and drives among the pines, golf, many excursions in the vicinity to various historic and ancient landmarks,—old churches, plantations, and the like,—the Pinehurst Garden Park, with its large variety of ornamental trees and shrubs, and the Pinehurst Tea Gardens where the tea plant is successfully grown. Twenty-two miles distant is Charleston, with all its attractions in and about the city. There are also opportunities for shooting and fishing.

The subjoined meteorological table affords an index of the various climatic features. It will be seen that the winter temperature is comparatively mild, the mean maximum and minimum temperatures not extreme, and a large majority of the days are sunny, so that one can be out of doors the most of the time. The mean average annual rainfall for nineteen years was 56.76 inches, and for the four years of the chart, 59.16 inches. On account of the character of the soil the ground is quickly dry after the heaviest rainfall. The average relative humidity appears high, but it is said that there is no sensation of dampness in the atmosphere. According to Dr. W. H. Prioleau, of Summerville (*Therapeutic Gazette*, September, 1897), the climate is most beneficial to invalids from October to May, "for during that time there is bright sunny weather, and the atmosphere changes are seldom so sudden as to cause any serious anxiety or discomfort." "The town is near enough to the sea coast," says the same authority, "to cause the atmosphere to lose the aridity of a sandy plain; at the same time sufficiently distant to be free from all dampness."

* CLIMATE OF SUMMERVILLE, S. C.—PERIOD OF OBSERVATION FROM JANUARY, 1899, TO JANUARY, 1903.

	November.	December.	January.	February.	March.	April.	July.	September.	Year.
Temperature—Degrees Fahr.									
Average mean	59.3°	47.5°	46.8°	46.6°	54.4°	59.2°	80.1°	72.5°	
Average maximum	79.5	74.7	74.8	76.2	81.2	83.7	96.2	91.0	
Average minimum	29.5	19.0	21.4	16.7	27.6	34.7	65.2	53.5	
Mean maximum	66.5	58.7	58.4	56.3	67.7	68.1	88.3	82.7	
Mean minimum	51.2	46.2	36.8	37.1	44.9	50.2	71.2	65.2	
Average daily range	15.3	12.5	21.6	19.2	22.8	17.9	17.1	17.5	
Average monthly range	51.2	55.0	53.4	57.4	53.6	49.0	31.0	37.5	
Humidity—									
(The humidity was recorded only a portion of the period.)

Prevailing direction	N. E.	S.W.-N.E.	S. W.	S., N. W.	S. W.	S. E.	S. W.	N. E.	N.E., S.W.
Weather—									
Average number of clear days	18.2	15.0	13.0	10.4	13.4	15.7	15.2	19.7	
Average number fair days	6.7	7.5	9.2	10.0	11.2	9.2	12.5	5.2	
Average number clear and fair days	24.9	22.5	22.2	20.4	24.6	24.9	27.7	24.9	
Average number cloudy days	5.0	8.2	8.8	7.6	6.4	5.0	3.2	5.0	

Frost occurs from November to April, with ice and occasional snow in the coldest months of the year.

* These data were obtained through the kindness of Dr. A. H. Hayden, of Summerville, S. C.

The diseases and conditions for which this climate is suitable are pulmonary tuberculosis in the early stage, laryngitis, bronchitis, asthma, influenza, neurasthenia, and insomnia. Further, it is a favorable place for a winter residence for the many who, for one reason or another, desire to escape the cold of the North or West. "I must admit," says Elizabeth Stuart Phelps, writing in *McClure's Magazine*, "that Summerville is a land of lovely dreams, with more conveniences and fewer discomforts, more tonic and less enervation than any other Southern health or pleasure resort I have seen. Roses run riot over it; its homes are gardens, and gardens are its homes. There the winds are laid. . . . There it is always dreamland, and there the knotted Northern nerves may relax and rest."

One can reach Summerville by various railroad routes or by water from New York to Charleston and from thence by rail. The time from New York by rail is twenty-four hours. *Edward O. Otis.*

SUMMIT SODA SPRINGS.—Placer County, California.

Post-Office.—Summit Soda Springs. Hotel and cottages.

Access.—Viâ Central Pacific Railroad to Summit station, thence by stage or carriage, twelve miles to the springs. The location is near the summit of the Sierra Nevada Mountains, at an altitude of 16,000 feet above the sea-level. The region is one of picturesque grandeur, and the magnificent view from the neighborhood of the springs is unobstructed for miles around. The air is pure, dry, and invigorating, being cool and pleasant all the summer. The springs are situated in an expansion at the head of a deep canyon, along which winds one of the forks of the American River. The hotels and cottages are pleasantly located, and good bathing facilities are at hand. Two analyses have been made. They are as follows:

One United States Gallon Contains:

Solids.	Dr. Winslow Anderson, 1888. Grains.	J. T. Randolph, 1878. Grains.
Sodium chloride	26.18	26.22
Sodium bicarbonate	4.11	....
Sodium carbonate	5.75	9.50
Potassium carbonate	.82	Trace.
Magnesium carbonate	4.05	4.20
Calcium bicarbonate	38.93	43.20
Calcium carbonate	6.55	....
Ferrous oxide	....	1.55
Ferrous carbonate	2.70	....
Borates	Trace.	....

Silica	1.94	2.06
Organic matter	Trace.	....
Total solids	92.16	88.68

Free carbonic acid gas, 187.25 cubic inches (saturated).

The water has antacid, diuretic, aperient, and tonic properties, and is useful in the treatment of dyspepsia, torpidity of the liver and bowels, Bright's disease, stone in the bladder, etc. *James K. Crook.*

SUNDEW. See *Droseraceæ.*

SUPERFŒTATION.—Ordinary multiple pregnancy is generally the result of the simultaneous fertilization of more than one ovule. Should such fecundation be *successive* instead of *simultaneous*, it is called *superimpregnation*. Of this, there are two varieties: (1) *Superfecundation*, which occurs when two (or more) ovules belonging to the *same* period of ovulation are impregnated by successive acts of coitus. (2) *Superfœtation*, which occurs when two or more ovules belonging to *successive* periods of ovulation are impregnated, so that a woman who is already pregnant becomes again pregnant a month or more later, and carries simultaneously in the uterus both these products of conception. Thus a second ovum is fertilized after the first has been developing for a month or more, and the two fœtuses continue to develop simultaneously and independently.

The term *superimpregnation* has been used in two senses: (1) as a generic term including both superfecundation and superfœtation; and (2) as synonymous with superfœtation or superfecundation. We believe the former to be the more correct usage, though the term might well be abolished.

Superfecundation is now well recognized, and needs no discussion. There have been reports of too many well-authenticated cases to allow of any doubt on this point. The most conclusive proofs are furnished by those cases in which a black woman has at the same time given birth to twins, of different colors, the one a mulatto and the other black, and whose features have unmistakably indicated their paternity. In many of these instances the mother has explained that both a white man and a black man had had intercourse with her within a short interval of each other. Similar, but not so frequent, are the reported cases in which a white woman has had intercourse successively with a white man and a black man, and has given birth to twins of different colors and races. Illustrative cases in abundance may be found in the pages of works on medical jurisprudence, notably those of Tidy and Beck.

But *superfœtation* has not been so readily admitted. Like other theories which have subsequently crystallized into facts and been accepted, the possibility of superfœtation has been alternately asserted and denied. Thus, according to Beck, Brassavolus, who lived between 1500 and 1555, said that he had known *superfœtation to be epidemic!!!* By later physicians, the possibility of superfœtation was generally accepted, and many cases were brought forward to support the claim; but it is doubtful how many of these cases would stand the test of a thorough investigation at the present day; and some of them are certainly capable of much simpler explanation. The next stage was that of vigorous denial. This view has been taken by Lusk, who says: "That impregnation can take place at two periods distant from one another—must be regarded as an inadmissible hypothesis, until physiologists shall succeed in demonstrating in a single instance, by the presence of corpora lutea of different ages, that ovulation ever occurs during pregnancy" ("Midwifery," 1896). No doubt ovulation does ordinarily cease during pregnancy; and this may be one of the reasons why there are so few cases of superfœtation. But that ovulation can occur during pregnancy has been demonstrated by Christopher (*Am. Jour. of Obstet.*, 1886), who also cites Slavjansky's case, as follows: "Professor Slavjansky, of St. Petersburg, in a laboriously exact paper in the *Annales de Gynécologie*, vol. ix., furnishes a report of a very interesting and instructive case. A woman, twenty-four years of age, had menstruated since her seventeenth year, and had been delivered of a child three years previous to her present pregnancy. Her last menstruation occurred November 5th, 1876, but conception is supposed to have taken place early in December. Death occurred March 23d, 1877, from a rupture of the left Fallopian tube, due to tubal pregnancy. The legal autopsy was made thirty hours after death, and the generative organs afterward given to Slavjansky for examination. He found on the left ovary a tumefaction which presented a cavity 1 to 3 cm. in diameter, and on microscopic examination presented all the characters of a Graafian follicle. The contents, which had been coagulated by alcohol, were carefully separated by a needle, and on examination under the microscope were found to be the cells of the discus proligerus, and within them was found the ovule with its eccentrically situated germinal vesicle and germinal spot clearly marked. In the cortical substance of this ovary were found numerous Graafian follicles in all degrees of development, from the primordial follicle up to the follicles of 0.3 cm. in diameter. A corpus luteum of 0.4 cm. in diameter was found immediately under the principal cavity. In the cortical substance of the right ovary were numerous follicles of varying degrees of development, one being 0.3 cm. in diameter. A recent corpus luteum 1 cm. in diameter was clearly outlined in the surrounding tissues." Of even more value, and apparently unassailable, is Cosentino's case: "A woman in the sixth month of pregnancy died of heart disease. The ovaries were subjected to a careful microscopic examination, and in them were found follicles in all stages of development; also one ruptured follicle of a diameter of 15 mm. with ragged margins and a rich arterial and venous network surrounding the theca folliculi. Between the granular layer and a lot of detritus a perfectly mature ovum with all of its elements was found" (quoted by Herzog, in Chicago *Medical Record*, July, 1898). Even more emphatic in his rejection of superfœtation is Kleinwächter; he says: "The whole claim as to superfœtation, however, collapses, because the base on which this alleged occurrence rests does not exist. As soon as pregnancy has occurred, ovulation ceases. Superfœtation, therefore, is a physiological impossibility. However, even if ovulation did take place, superfœtation nevertheless could not occur, since the sperma, in consequence of the plug of mucus in the cervix, cannot reach the ovum. This plug of mucus which forms in the cervix, the proliferation of the mucosa of the uterus, the fusion of the decidua reflexa with the decidua vera, which takes place in the twelfth week, make it impossible, even if an ovum should be discharged from the uterus, that it could come into contact with the sperma deposited in the vagina" (Herzog, *ut supra*). But these objections are more fanciful than real, for it has now been proved that: (1) Ovulation can occur during pregnancy (*vide supra*). (2) The plug of mucus which is found in the cervix of the pregnant uterus is also found in the cervix of the non-pregnant uterus, and, therefore, if it were a bar to superfœtation, it would also prevent pregnancy! Indeed, it has been asserted that, so far from this plug of mucus preventing the entrance of the spermatozoa, it, by absorption, rather assists them into the uterus. (3) The fusion of the decidua vera and the decidua reflexa occurs "at the fourth month" (J. Whitridge Williams, "Obstetrics"), and until this fusion occurs there is abundant opportunity for the spermatozoa to pass upward toward the Fallopian tube.

At the present day, both the possibility and the probability of superfœtation are fully admitted; that it is of frequent occurrence, or that the majority of the cases formerly reported under this heading are correctly designated, is not conceded. It must be remembered that superfœtation is neither normal nor physiological; it is a pathological condition. In an ordinary normal pregnancy we note the following (among other) characteristics: (1) It is single; (2) it is intra-uterine; (3) menstruation and ovulation both cease; (4) the uterus is neither bifid nor septate, but single. Now, variation in any of these conditions may produce pathological or abnormal results; and superfœtation is one such pathological variation. The possible results of superfœtation are two: *either* two children equally well developed, but born at different times; *or* the birth of twins, one of which is developed and the other not. Those who deny the possibility of superfœtation have explained these conditions as being due *either* (1) to an ordinary twin pregnancy, or a superfecundation, in which one fœtus was "crowded," or for some other reason did not obtain adequate nutrition during gestation, and was therefore not properly developed; *or* (2) to an ordinary twin pregnancy or superfecundation in which one ovum became blighted, and possibly suffered compression and partial mummification (= *fœtus papyraceus*); *or* (3) to a bifid uterus, in which one ovum was developed in each half.

There can be no doubt that many of the earlier reported cases of superfœtation can be explained as above; but there still remain some that are intelligible only on the ground of superfœtation. Thus, where viable children are born at an interval of *four months*, and the uterus is not double, there is at present no explanation to be offered beyond the one that forms the subject of this article. Tidy, in his "Legal Medicine," quotes one such case from Naphey: "Mary Anne Bigaud, at thirty-seven, gave birth, on April 30th, 1748, to a full-term mature boy, which survived its birth two and one-half months, and to a second mature child (girl) on September 16th, 1748, which lived for one year. The mother was proved after her death not to have had a double uterus. (This case is vouched for by Professor Eisenman, and by Leriche, surgeon-major of the Strasbourg Military Hospital)." And several such cases are given by Bonnar (*Edin. Med. Jour.*, January, 1865), "cases that prove, as far as anything of the sort can prove, that superfœtation is a positive fact."

R. J. E. Scott.

SUPRARENAL BODIES, PATHOLOGY OF.—Inasmuch as this subject has already been discussed to some extent in the article on *Addison's Disease*, only those conditions will be mentioned here which were not considered under that head.

Anomalies and Malformations.—Total absence of the adrenals has been reported, but in some of the cases it is impossible to state positively that the absence was congenital and not the result of an extreme atrophy. Congenital absence and hypoplasia have, however, been observed in cases of hemicephalus and anencephalus and in certain forms of malformations of the genito-urinary organs. According to Zander, the adrenal hypoplasia is associated only with defects of the frontal lobes. Aplasia of the medullary portion of the suprarenals has been seen in cases of chronic hydrocephalus, but the connection between these conditions is not clear. Fusion into one organ, abnormality of shape and form, displacement, separation into several bodies, and hypertrophy have been described. As a rule, the malformations of the suprarenals bear no relation to those of the kidneys, though in one case reported of horseshoe kidney there were four adrenals. Malformations of these organs appear to stand in a closer relationship with those of the sexual glands. Marchand has reported a case of marked hyperplasia of the suprarenals and of the accessory suprarenal structures in the broad ligament, in a case of rudimentary development of the ovaries and external hermaphrodism.

Accessory Suprarenals (Adrenal Rests).—Small isolated portions of adrenal tissue, varying in size from a pinhead to a cherry, are of very frequent occurrence in the immediate neighborhood of the main organ, lying in the peri-adrenal connective tissue, in the solar plexus, in or under the kidney capsule, in the kidney substance, or even in the liver. Small bodies consisting of tissue resembling that of the adrenal cortex are also found in the broad ligament, along the spermatic vessels, in the inguinal canal, on the spermatic cord, and in the retroperitoneal connective tissue. By a number of authors the adrenal tissue found in the last-named regions is regarded as analogous to the suprarenal organs of the lower vertebrates, the main adrenal organs of man representing the interrenal bodies of these animals. Marchand having been the first to observe their presence in the broad ligament, they have been designated the "adrenals of Marchand" ("Marchand'sche Nebennieren"). By other writers they are regarded as misplaced adrenal tissue referable to some disturbance of development. The chief pathological importance of these bodies is the possibility of the development in them of the same form of new growths as arise in the adrenals themselves, or in the adrenal "rests" of the kidney, liver, etc. Adrenal tissue has been found in a cystic tumor of the broad ligament. The small masses of adrenal tissue found in the inguinal canal or upon the spermatic cord have been mistaken for lipomata. It is also possible that these accessory bodies may undergo a compensatory hypertrophy in the case of destruction of the main organs in early life. Accessory adrenals or "adrenal rests" are of a yellowish color, and have a fatty shine. From their close resemblance to fat tissue they have frequently been mistaken for lipomata. In the great majority of cases the microscopical structure resembles that of the fascicular zone of the adrenal cortex; and very rarely do these bodies contain cells resembling those of the medullary portion of the organ.

Circulatory Disturbances.—Chronic passive congestion of the systemic veins gives rise to a *passive congestion* of the adrenals, which in consequence are enlarged and of a deep brownish-red color. *Hemorrhage* into the adrenals may occur in congenital or acquired hæmophilia, in pernicious anæmia, in leukæmia, after thrombosis of the veins, and as a result of trauma or of general passive congestion. Severe injuries, such as fracture of the spine, are frequently associated with hemorrhage into or about the adrenals. Hemorrhage into the suprarenals appears to be of frequent occurrence in the new-born. According to Mattei and Spencer, some degree of congestion of the suprarenals is always present in the new-born. As the border line between slight hemorrhage and congestion is not well defined, it is very probable that some cases of congestion have been regarded as hemorrhage. If not confirmed by microscopical examination, no diagnosis of adrenal hemorrhage should be made unless distinct hemorrhagic spots or bands are seen in the tissue of the organ, or unless the hemorrhage is so extensive as to convert the organ into a cyst filled with fluid or coagulated blood.

Hamill has collected ninety cases of adrenal hemorrhage occurring in the new-born. Various causes are given, but it is probable that the most common etiological factor in still-born children is prolonged and difficult labor requiring manipulation, especially in the case of breech delivery. In some of the infants dying within a few days after birth, the hemorrhage may be the result of injuries received during labor, but in the great majority of such cases some form of infection is to be regarded as the cause; in practically all cases dying after the tenth day some form of infection produces the condition. Of the ninety cases collected by Hamill, twenty-eight were seen in still-born children, twenty-seven between birth and the separation of the cord, and eleven after the latter event. The hemorrhage may be unilateral or bilateral, the lesion apparently being more common upon the right side, this being due probably to anatomical reasons. The hemorrhage is usually into the medullary portion, and the appearances vary with the amount of extravasation. The gland may be greatly enlarged and the blood may break through into the peritoneal cavity when the extravasation is large. When not immediately fatal the hemorrhage may lead to cystic or fibrous change in the gland, and it has been suggested that possibly some of the cases of Addison's disease in which a marked fibrosis of the gland was found may have been the result of a hemorrhage occurring at an earlier period. Old hemorrhages may become calcified.

Hemorrhagic infarction of the suprarenal due to thrombosis of the central vein has been reported as occurring in a child of eleven months. The etiology of the thrombus was not clear, but it was thought to be marantic in origin. A similar condition may follow thrombosis of the renal vein.

RETROGRADE CHANGES.—Simple *atrophy* of the adrenals occurs in old age and in cachectic conditions. A marked atrophy has been observed in cases of Addison's disease. The atrophic organs may be no larger than peas. Associated with the atrophy of old age there is frequently seen a marked pigmentation of the medulla.

Necrosis of the adrenals occurs in tuberculosis, eclampsia, in certain infections and intoxications, in extreme passive congestion, and following hemorrhage and thrombosis of the central vein. Focal necrosis has been observed in malaria. Inasmuch as the medulla of the adrenals very quickly undergoes a post-mortem disintegration, such change occurring even within from half an hour to one hour after death, the presence of a soft brownish substance in a cyst-like cavity representing the medulla should not be mistaken for a pathological condition. The post-mortem change may be recognized by the absence of hemorrhage or of changes in the cortex. The cyst-like cavities formed by post-mortem change gave rise to the designation "suprarenal capsule."

Cloudy swelling of the cells of the adrenals occurs in severe general intoxications.

Fat in the form of small droplets is almost constantly present in the cortical cells of the adult adrenal, particularly in those of the fascicular zone. Large droplets are often present. Excessive fatty change has been described as occurring in marasmic infants and in cases of congenital syphilis, and has also been regarded as a cause of Addison's disease.

Amyloid change is of frequent occurrence in the adrenals in cases of general amyloidosis. The amyloid is deposited in the walls of the blood-vessels and in the connective tissue. The parenchymatous cells become atrophic and may entirely disappear, the organ becoming larger, hard, waxy, and bluish-gray in color. The cortex usually shows the greatest change, but the medulla is not infrequently affected alone or coincidently. Amyloid change of the adrenals has also been regarded as a cause of Addison's disease.

Calcification of the adrenals may follow caseous necrosis or hemorrhage, and is not infrequently present without any signs of other pathological changes.

Pigmentation of the cells of the medulla is increased in old age and in conditions of excessive blood destruction.

Inflammation.—Simple inflammation of the adrenals is very rare. Metastatic abscesses occur in pyæmia and may lead to total destruction of the organ; they may rupture into the intestine or into the retroperitoneal connective tissue. Fibrosis of the adrenals due to chronic interstitial inflammation has been reported, but the nature of these cases is obscure. Such changes have also been reported as occurring in Addison's disease.

TUBERCULOSIS.—Miliary tubercles may be found in the adrenals, but tuberculosis of these organs is usually of the fibro-caseous type. The glands in the latter condition become enlarged, hard, and often nodular. The capsule is thickened, the parenchyma either wholly or in part replaced by a firm, dry, cheesy, yellowish or a soft pus-like material. About the capsule there may be present a large amount of scar tissue involving the semilunar ganglia. Tubercle bacilli are found in the caseous areas. Calcification or liquefaction may follow the caseation. In many cases only one organ is affected. The condition is rarely primary, but is in the great majority of cases secondary to a chronic pulmonary tuberculosis. When primary it may form the starting-point for a tuberculosis of the peritoneum. (See *Addison's Disease*.)

SYPHILIS.—Gummata have been found in the adrenals, and in both congenital and acquired syphilis thickening of the blood-vessels may occur. Total fatty degeneration has also been described as occurring in cases of congenital syphilis.

ACTINOMYCOSIS of the adrenals has been reported as extending from actinomycotic processes in the liver.

PROGRESSIVE CHANGES.—*Hypertrophy* and *hyperplasia* of adrenal tissue may occur in young individuals after loss of the main organ or organs. In the latter case the adrenals of Marchand or other accessory adrenal tissue may undergo a compensatory hypertrophy. The diffuse hyperplasias are very rare, but localized nodular hyperplasias are frequent.

TUMORS.—The most common form of tumor is that arising from adrenal rests (see *Hypernephroma*). These growths may reach a very large size, and occasionally present the appearance of a large cyst filled with a brownish pultaceous material produced by the extensive fatty degeneration characteristic of these growths. The smaller growths appear as yellowish nodules resembling fat tissue. The microscopical picture is usually that of the fascicular zone of the cortex, but growths consisting of medullary tissue have also been described. Though frequently benign except for size, the hypernephromas of the adrenals may through continued atypical growth take on the characteristics of a carcinoma. It is probable that the majority of the malignant tumors arising primarily in the adrenals, which have been reported as carcinomata, in reality belonged to the hypernephromata, though it is also possible that tumors of the type of carcinoma may be primary in this organ. The term *adenoma* or *malignant adenoma* is frequently applied to these growths (*struma suprarenalis*); at present they are classed with the hypernephromata.

Sarcoma.—Melanotic and non-pigmented sarcomata have been reported as primary in the adrenals. Lym phosarcoma is of rare occurrence. There exist in the literature numerous accounts of sarcoma of the adrenal, but it is very probable that these tumors belonged to the hypernephromata and not to the true sarcomata. This is especially true of the cases reported as "malignant tumor," "adenosarcoma," "alveolar sarcoma," "carcinoma," etc. Through the occurrence of hemorrhages the growths may become very large, and occasionally break into the veins and set up metastases. The latter are found chiefly in the lungs.

Gliomata and *neuromata* of the adrenals have been described, but the true nature of the cases is uncertain. They arise from the medulla or from the sympathetic system.

Connective-tissue growths are very rare. Cystic lymphangiomata have been very rarely observed. Ganglionic fibromyoangioma has also been described.

Secondary tumors (sarcoma and carcinoma) are of not infrequent occurrence. Metastasis takes place usually through the lymphatics. Secondary carcinoma may be associated with Addison's disease.

Parasites.—In very rare cases *echinococcus* has been found in the adrenals. *Aldred Scott Warthin.*

SUPRARENAL CAPSULE, EXTRACT OF. See *Adrenalin*, and *Organotherapy.*

SUSPENSORY BANDAGES are employed for prophylactic purposes when the scrotum and its contents are normal, but exposed to injury or disease. Thus they are recommended to men whose occupation compels them to stand for hours in the upright position, to lift heavy weights, to take severe physical exercise, or to ride a horse or a bicycle for hours at a time. Athletes usually wear bandages technically called "jock-straps" in place of suspensories. These "jock-straps," however, while immobilizing the external genitals, drag them upward, and, in fixing them upon the pubes, may produce abnormal pressure of the scrotal contents, and expose them to the injuries which they are intended to prevent. Among the prophylactic uses of suspensory bandages, they are recommended in gonorrhœa to prevent epididymitis and orchitis. Experience, however, has proven that they are not always effective in this regard. The therapeutic uses of suspensory bandages are as varied as are the diseases which affect the scrotum and its contents. In general depressed states, where relaxation of the scrotum causes it to hang down below its normal level, a well-fitting and properly adjusted suspensory bandage gives the organs within it the needed support. In local conditions, such as scrotal dermatoses, it serves to immobilize the sac and thus compels any medicaments which may be applied to the skin to remain in direct contact therewith. In varicocele of a minor degree it oftentimes renders operation unnecessary. In funiculitis, epididymitis, orchitis, and orcho-epididymitis, when the swelling is not too great to be controlled by a suspensory bandage, it serves its purpose admirably. When the swellings in these diseases are very great, they require modifications of suspensory bandages, called compressors, such as the Miliano, Zeissl, Langlebert, Casper, and other scrotal compressors. These modifications not only support the scrotum firmly against the ascending rami of the pubis, but, having a firm, strong bag with lace-strings, they render it possible to subject the scrotum and its contents to uniform compression. It is essential to suspensories and compressors that traction should be exerted in a posterior direction upon the lower (posterior) apex of the bag. This traction is made by means of counter-straps. If these straps are omitted, as they sometimes are, especially in the cheaper forms of suspensories, these contrivances then become useless and even at times injurious. Firm support and compression are not possible without these counter-straps. When they are absent the scrotum is dragged upward and forward by the waist-band, and the posterior margin of the bag is likely to cut into the posterior surface of the scrotum. Many forms of excellent suspensory bandages are made, but no one form can be recommended for all prophylactic or therapeutic uses. The individual conformation of the external genitals varies as much as does that of the hand or foot. Suspensory bandages must therefore be "fitted" to the genitals, with consideration for the individual peculiarities as well as for the object to be attained. The inflexible rules regarding the effective use of suspensory bandages are, first, that they must not produce the slightest discomfort, and next, that they must instantaneously give at least marked, if not entire, relief from pain. If these ends are not attained, the bandage employed is not applicable to the case or has been defectively applied. In epididymitis, when the cord is not much involved, strapping the testicle by Fricke's method often enhances to a marked degree the value of a suspensory bandage. It must be remembered, however, that the application of strips of adhesive plaster for the accomplishment of the desired end is painful, unless it be done by an operator of great experience in the use of this form of dressing. When it is properly applied this dressing promptly reduces swelling and pain, and renders the patient entirely willing to have the operation repeated as often as may seem desirable. Gerson, of Berlin (*Berliner klinische Wochenschrift*, No. 3, 1897), devised "scrotal elevating strips" as a substitute for suspensory bandages. These strips (*Suspensionsbinden*) are elastic, adhesive bandages, with the upper margin softly fringed. Before applying them it is desirable to empty the lower part of the scrotum as much as possible by crowding the testicle firmly up against the external ring. In a certain number of cases these strips prove successful, and as it is an easy matter to apply them they may well be recommended for trial.

Ferd. C. Valentine.

SUTHERLAND SPRINGS.—Wilson County, Texas.

Post-Office.—Sutherland Springs. Hotel and boarding-houses.

Access.—From San Antonio viâ the San Antonio and Gulf Railroad, thirty miles distant.

The resort is pleasantly located on the Rio Cibolo, at an elevation of about 400 feet above the sea-level. The surrounding country is of a gently undulating character and presents much pleasing scenery of a mild and tranquil character. This part of the State is celebrated for its genial climate and its freedom from malarial and miasmatic disorders. At the date of our correspondent's letter (December 27th), the flowers were in full bloom out of doors and the gardens were as green as in summer. There is no ice at any time, and the frosts are seldom sufficiently severe to cause the trees to shed their leaves. Many persons who begin the baths during the summer continue them during the winter months, as it is seldom cold enough to interfere with this pastime. No analysis of the water has been made, but the numerous springs are said to offer a variety of therapeutic properties—tonic, alterative, astringent, laxative, diuretic, etc. This combination of valuable spring waters with a mild, dry, equable climate makes the location a very attractive one for a large class of sufferers from various ailments. It is said that a fine modern hotel will soon be built. *James K. Crook.*

SUTURES.—Suture Materials.—The materials used for sutures are very varied. The ones most employed are silk, catgut, silkworm gut, silver wire, horse-hair, and kangaroo tendon.

Silk, not being absorbable, is not good, except in the smaller sizes, for deep sutures or ligatures, and finds its use chiefly in uniting the skin and in intestinal work. It is also used for tying off pedicles where great strength is requisite. It is best sterilized by boiling it on spools in alcohol or in a one-per-cent. solution of carbonate of sodium. The small sizes are usually dyed black for easier detection. When the suture is small it may be cheapsulated and thus remain in the tissues indefinitely; but, on the other hand, it may give rise at any time to inflammation and the formation of a fistula.

Catgut is used largely for deep sutures, *i.e.*, those which are buried in the deeper parts. They are absorbed

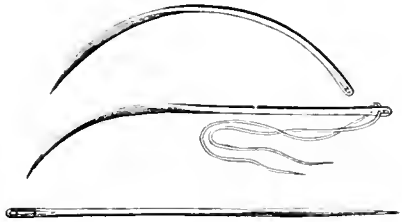

FIG. 4564.—Surgical Needles.

and thus produce no subsequent irritation, which is possible in non-absorbable materials. In order to prevent too rapid absorption the catgut may be "chromicized." Chromicized catgut may remain unabsorbed for as long a period as from two to six weeks. The gut is soaked in ether for twenty-four hours and placed for twenty-four hours more in a four-per-cent. solution of chromic acid in water. The gut is now dried in a hot-air sterilizer and disinfected by one of the usual methods. The most serious objection to catgut as a suture material is the difficulty of sterilizing it completely. This difficulty has given rise to a great number of methods of disinfection. Boiling in ninety-five-per-cent. alcohol for an hour with the use of a still is a very satisfactory method. For other methods, see under *Dressings (Surgical)*. Catgut is not so satisfactory as silk for suturing the skin.

FIG. 4565.—Interrupted suture.

Silkworm gut is an excellent material for tension sutures, but should not be used for buried sutures, as it has sharp ends and is non-absorbable. It is used extensively in perineum and cervix operations. It is prepared by boiling it in alcohol or water. It may be dyed black for easier detection. When boiled too often it breaks easily if drawn tight.

Silver wire is used in holding bone fragments together and also as a tension suture for the skin. The suture is twisted on itself and then it holds the parts in contact. It can be satisfactorily sterilized by boiling it in water.

Horse-hair is occasionally used for the skin when there is not great tension on the edges of the wound. It is sterilized by boiling it in water or alcohol.

Kangaroo tendon is obtained from the kangaroo's tail or leg. It is very strong and pliable. It can be satisfactorily used for buried sutures, and has found its chief employment in hernia operations. It should be chromicized. It is finally absorbed, but only after several weeks.

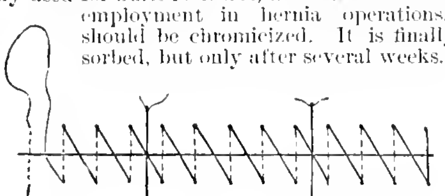

FIG. 4566.—Continuous Suture.

Surgical Needles.—These are of different sizes and shapes (Fig. 4564). They may be straight or curved, round or flat. Hagedorn needles which are flat and have a sharp cutting edge are in very general use. In intestinal work round needles are preferable, as they do not cut the thin tissues, causing the suture to pull out. For suturing deeper parts, as in pelvic operations, a needle-holder is useful, and there are many forms. Needles are sterilized by boiling or by placing them in carbolic acid, 1 to 20, for fifteen or twenty minutes.

THE DIFFERENT KINDS OF SUTURES.—Wounds can be united by a variety of forms of suture.

Interrupted Suture (Fig. 4565).—This is the usual form of suture for uniting the edges of the skin. The needle

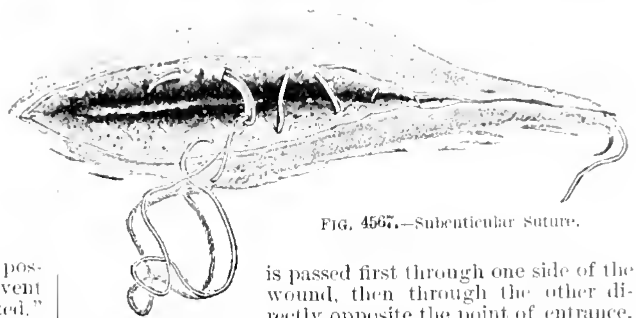

FIG. 4567.—Subcuticular Suture.

is passed first through one side of the wound, then through the other directly opposite the point of entrance. The two ends are tied with a reef-knot and cut short. The knot should be on one side of the line of the wound. When there is tension of the wound the so-called tension sutures are used, which are inserted at a further distance from the edges of the wound than ordinary coaptation sutures. The interrupted sutures should be placed near enough together to insure good approximation of the edges of the wound. The suture is removed by cutting the thread close to the skin and pulling on the knot. Medium-sized silk is generally employed for the skin.

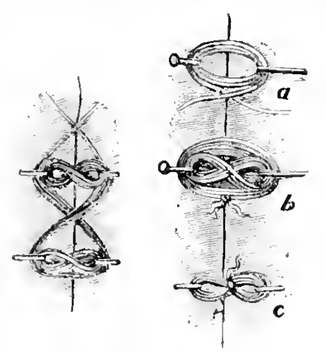

FIG. 4568.—Figure-of-Eight Sutures.

Continuous Suture (Fig. 4566).—This is begun at one end of the wound. Instead of cutting the thread after the first suture, the latter is continued throughout the whole length of the wound. The needle is inserted at points directly opposite each other. In this way the visible part of the thread forms a row of parallel oblique lines and the invisible part a row of transverse lines. The suture is tied by tying the double thread on one side to the single portion on the opposite. This suture can be inserted more rapidly than the interrupted, and is well adapted for long wounds.

Subcuticular Suture (Fig. 4567).—This is a catgut suture in which the curved needle is passed in and out below and parallel to the skin and then drawn up tight so as to bring the skin surfaces in contact. The advantages of it are that it leaves only a small scar and minimizes the danger of stitch hole abscesses from penetration of the skin with its bacteria.

FIG. 4569.—Mattress or Quilt Suture.

The Figure-of-Eight Suture (Fig. 4568) is made by transfixing both edges of the incision with a short pin and twisting a thread about the two ends. This is sometimes used in harelip operations.

Mattress or Quilt Suture (Fig. 4569).—In this variety the needle is passed through each side twice, and in this

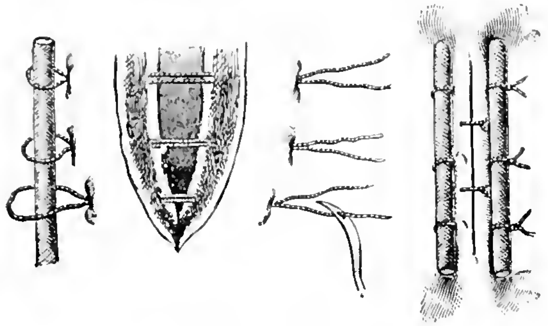

Fig. 4570.—The Quilled Suture.

way a firmer hold is obtained. It can be either interrupted or continuous.

Quilled Suture (Fig. 4570).—This is used in case of tension on the edges. A double thread is passed through both edges at a good distance from the same. Into the loop on one side a piece of catheter, gauze, or drainage tube is inserted and the free ends on the opposite side are tied about the same material. The edges may be brought into closer apposition by another row of sutures inserted close to the edges.

Secondary Suture.—If it is desirable to bring together a wound which is granulating, we employ secondary sut-

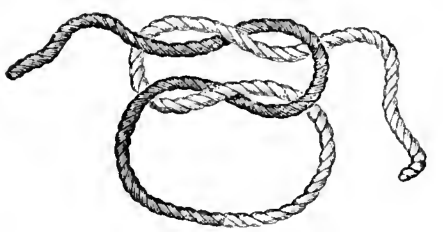

Fig. 4571.—The "Reef" Knot.

ure. This is also employed for wounds which, on account of their depth or of hemorrhage, were first packed. Any of the above forms of suture can be employed for this purpose.

Knots.—The knot used for tying sutures is usually the reef-knot (Fig. 4571). This is preferable to the granny knot (Fig. 4572), which is more likely to slip and become untied. The square knot can be combined with the so-

Fig. 4572.—The "Granny" Knot.

called surgeon's knot (Fig. 4573), in which the ends of the thread are twisted about each other twice instead of once.

Intestinal Sutures.—For intestinal work the small sizes of silk are employed and either the straight or the curved needle. An ordinary strong needle answers the purpose. The main object is to bring peritoneal surfaces in contact,

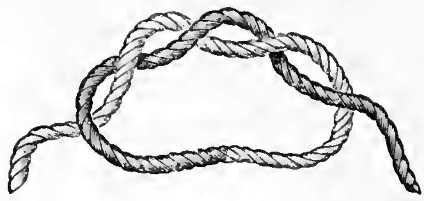

Fig. 4573.—Surgeon's Knot.

which then adhere promptly and prevent the escape of intestinal contents. The sutures may be interrupted or continuous.

Lembert Suture (Fig. 4574).—The needle penetrates a fold of the intestinal coat consisting of the peritoneal, muscular, and submucous layers without entering the

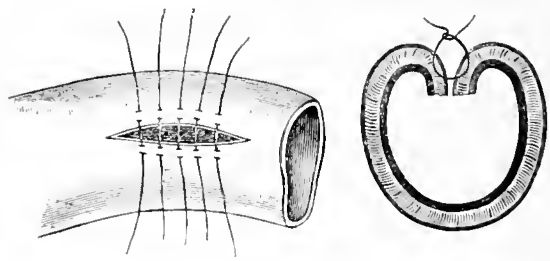

Fig. 4574.—Lembert Suture.

mucosa. The fold is about one tenth of an inch wide, and is situated about one-eighth of an inch from the edge. A similar edge is picked up on the opposite side and the suture is drawn tight, thus inverting the edges and bringing serous surfaces in contact. This is the usual form of intestinal suture and answers the purpose admirably. A second row outside the first may be added and in this way the edges inverted still more.

The Czerny-Lembert Suture (Fig. 4575) is merely a Lembert suture reinforced by a deep row bringing together the edges of the mucous membrane. These latter sutures are knotted inside or outside the bowel.

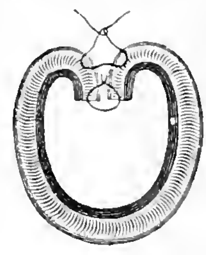

Fig. 4575.—The Czerny-Lembert Suture.

Halsted Suture.—This is supposed to have the advantage of not tearing so readily as most sutures do when subjected to tension. It is a Lembert suture which passes through the wall of the intestine parallel with the line of incision instead of at right angles to it.

Benjamin T. Tilton.

SUWANEE SULPHUR SPRINGS.—Suwanee County, Florida.

Post-Office.—Suwanee. Hotel, Suwanee Springs Hotel.

Access from all points viâ Savannah, Florida, and Western Railroad to Suwanee, thence one mile to springs.

The famous Suwanee River is now open as a regular tourist route, and the traveller for health or pleasure can with ease and comfort visit this romantic stream of legend and song and the attractive resorts located along its banks. The Suwanee Springs Hotel property consists of a beautiful park of massive live oaks and tall pines to the extent of one hundred acres situated along the river banks and on the picturesque bluffs. In the park the company has built a handsome hotel and eighteen comfortably furnished and conveniently appointed cottages. The visitor need therefore have no fear of being subjected to the usual discomforts of a newly settled country. The buildings are well equipped with an excellent system of water works, and the sanitary appointments are of the first class. The water from the springs is supplied, either hot or cold, by pipes directly from the fountains to the rooms. The springs are located about two hundred yards from the hotel, and immediately on the banks of the river. They boil up from the ground at a rate of forty-five thousand gallons per hour, and the water exhales a strong sulphurous odor. Bathhouses are conveniently located along the margins of the springs. An unvarying temperature of the water, of 74° F., enables the visitor to bathe in the springs at any season without ill effects. An analysis of the water by Professors Chandler and Pellew, of New York, in 1893, resulted as follows: One United States gallon contains (solids): Sodium chloride, gr. 0.62; potassium sulphate, gr. 0.60; calcium sulphate, gr. 1.78; sodium bicarbonate, gr. 0.96; calcium bicarbonate, gr. 11.02; magnesium bicarbonate, gr. 3.48; oxide of iron and alumina, gr. 0.15; silica, gr. 0.81; organic and volatile matter, gr. 2.19. Total solids, 21.61 grains. The waters are quite heavily charged with sulphureted hydrogen gas, to which they owe much of their virtue. Rheumatism, nervous disorders, dyspepsia, and diseases of the liver, kidneys, and blood are benefited by the waters and baths. The neighborhood holds forth many attractions to the tourist, not the least being the poetic old Suwanee, which is said to possess more elbows, curves, and angles in a shorter space than any other river in the world. Its banks are carpeted with ferns and mosses, and its dark but clear waters are overarched by a luxuriant tangle of umbrageous foliage. "A trip through the tortuous windings of this stream is indeed one of the most romantic that can be imagined, and when seated in a rowboat on a clear moonlight evening, floating over the placid surface of the dear old river, one can well imagine the sentiment that inspired the poet who has made the name of Suwanee so famous."

James K. Crook.

SWEAT. See *Skin, Functions of.*

SWEET CHALYBEATE SPRINGS.—Alleghany County, Virginia.

Post-Office.—Sweet Chalybeate Springs.

Access.—Viâ Chesapeake and Ohio Railroad to Alleghany Station, thence a drive of nine miles to the springs.

These well-known springs are ensconced in a lovely valley on the backbone of the Alleghany Mountains, at an elevation of 3,000 feet above the sea. The location is in the midst of the "Springs Region," and whatever may be said regarding the salubrity of climate, the charm of scenery, and the general attractiveness of the Old Dominion mountain resorts, may be fittingly applied to these springs and their environments. Among the more immediate desirable features may be mentioned a comfortable and tidy hotel, a commodious bathing establishment with facilities for hot and cold mineral-water baths, enclosed pools for plunge-bathing, etc. The section round about abounds in deer and other mountain game, while the streams afford excellent fishing. The springs, formerly known as the Red Sweet Springs, are situated in one of the most beautiful valleys of Virginia. So far as chemical composition is concerned, their waters do not show any very marked differences. The combined flow of the four is about forty-eight thousand gallons per hour. The following analysis was made by Prof. W. B. Rogers: One United States gallon contains (solids): Magnesium carbonate, gr. 2.70; sodium sulphate, gr. 3.23; calcium sulphate, gr. 32.88; magnesium sulphate, gr. 7.18; sodium chloride, gr. 0.09; magnesium chloride, gr. 1.57; calcium chloride, gr. 0.02; iron sesquioxide, gr. 0.73. Total, 48.40 grains. Gases: Carbonic acid, cub. in. 106.49; sulphureted hydrogen, a trace; oxygen, cub. in. 0.46; nitrogen, cub. in. 0.59.

A second analysis, by Professor Rowelle, shows four grains of iron (in combination) to the gallon. This is a very good calcic-chalybeate water. Its taste is somewhat sweet, but ferruginous. Its temperature at the fountain is about 75° F. The water is beneficially employed in anæmia, chlorosis, leucorrhœa, and other conditions indicating an impoverished state of the blood. It has also proved efficacious in neuralgia and gastralgia.

James K. Crook.

SWEET SPRINGS.—Saline County, Missouri.

Post-Office.—Brownsville. Hotel.

Access.—Viâ Sedalia and Lexington branch of the Missouri Pacific Railroad to Brownsville, thence one mile to springs.

The location is fifteen miles from the Missouri Blue Lick Springs.

These springs are five in number and have a flow of 224,000 gallons hourly. The temperature of the water is 54° F. Analyses of two of the springs have been made by Prof. Charles P. Williams:

One United States Gallon Contains:

Solids.	Akesion Spring. Grains.	Sweet Springs. Grains.
Calcium carbonate	40.25	9.56
Iron carbonate	.27	.57
Manganese carbonate	.20	Trace.
Sodium sulphate	2.61	....
Calcium sulphate	57.93	9.46
Barium sulphate	8.15	....
Calcium phosphate	.24	....
Magnesium nitrate	.18	....
Ammonium nitrate	1.17	....
Sodium chloride	756.11	86.92
Calcium chloride	74.79	14.72
Potassium chloride	28.56	3.40
Magnesium chloride	87.32	22.29
Lithium chloride	.30	.05
Magnesium bromide	.13	.12
Aluminum oxide	.17	.09
Silica	.51	1.08
Organic matter	3.05	4.01
Total	1,061.94	152.27

It will be observed that there is a great difference in the strength of these waters, the Akesion Spring being much more potent. The spring also contains a considerable amount of sulphureted hydrogen. It is especially recommended for diseases of the liver. The water of the Sweet Springs is recommended for diseases of the kidneys and bladder. An excellent bathing establishment is maintained at the springs, baths being supplied by water from the salt-sulphur spring, five miles distant. There are also white and black sulphur springs in the neighborhood.

James K. Crook.

SYCOSIS.—(Synonyms: Folliculitis et perifolliculitis barbæ; sycosis non-parasitica.) Sycosis is a disease of the skin that primarily affects the hair follicles. Most of the cases occur on the bearded portion of the face, but it may occur anywhere where there are coarse hairs, as on the scalp, eyebrows, axillæ, pubes, and even on the limbs of coarse-haired individuals. It has been called barber's itch, which is wrong, as that is ringworm of the beard. The term "non-parasitic sycosis" is also erroneous, as we now know that the disease is parasitic, though not due to the trichophyton fungus.

Symptoms.—*First, as it occurs on the face.* The disease begins by the eruption of a number of red, inflammatory, conical papules or nodules scattered over the whole or part of the bearded portion of the face. The lesions are discrete, and it will be noticed that each one is pierced in its centre by a hair. The skin between the lesions is unaffected. If the onset is very violent, so that a very large number of hairs are affected, the individual zones of redness will meet and then the whole of the affected area will be reddened and somewhat swollen. The lesions vary in size from that of a millet seed to that of a pea. Unless the disease is promptly relieved by treatment the papules give place to pustules, which likewise are pierced by hairs. The pustules show no tendency to run together and form patches as do those of eczema. After a time the pustules dry up and small crusts from about the hairs. If the disease is very intense infiltrated patches will form, and, instead of pustules, there may be abscesses. New papules continue to form and undergo their evolution into pustules, so that we find both forms of lesions present at the same time. The hairs in the pustules early lose their lustre. While at first firmly seated in their follicles so that attempts at depilation are painful, when the pustules are fully formed the hairs come out easily and without much if any pain. When the hairs are extracted early their root sheaths appear as glassy cylinders. After the pustules form the root sheaths will be yellowish and swollen with pus. While usually the hair is not permanently damaged, in chronic cases the hair papillæ are destroyed, the beard is thinned, and small cicatrices are seen.

The course of the disease is chronic, marked by relapses, the disease being at one time apparently cured, and then breaking out again with renewed violence.

Any part of the bearded portion of the face may be attacked. The disease is specially common on the upper lip. Usually there will be found at the same time a catarrhal or purulent discharge from the nose. The cheeks are the parts next most frequently affected, either one or both. The disease may occur symmetrically. It may be limited to a single area. As a rule it does not occur below the angle of the jaw. If it does occur there it is usually by extension from the cheeks. With it there is no eruption upon the non hairy parts of the face. Not uncommonly the eyebrows and the eye-lashes are affected at the same time as the cheeks.

There is little if any itching, the patient complaining rather of a feeling of soreness, distention, or burning.

Secondly, as it occurs on other parts. On the eyebrows and pubes and in the axillæ the appearances are similar to what obtains on the face, and the course of the disease is the same. On the scalp we meet with the characteristic papules and pustules pierced by hairs. When the disease occurs on the limbs (and it is mostly on the legs that it occurs), we find the same lesions; but, as the hair is more sparse, there is not the same tendency to form diffuse patches, the lesions remaining discrete throughout.

ETIOLOGY.—There is no doubt that the disease is parasitic. The majority of investigators ascribe its origin to the invasion of the hair follicles by the staphylococcus aureus et albus. Sabouraud states that it is due to the staphylococcus aureus alone. Unna teaches that there are two varieties of the disease, one of which he names the coccogenic, being due to the staphylococcus aureus et albus; and the other bacilligenic, being due to an organism which he calls *bacillus sycosiferus fœtidus.*

The disease is contagious, and barber shops are, without doubt, a frequent source of contagion. Like many other diseases due to micro-organisms, there are two factors at work—one the predisposing cause, the character of the soil; and the other the exciting cause, the micro-organism. Eczema is sometimes the forerunner of sycosis. Other predisposing agencies are irritant applications to the skin, such as mustard or other poultices, intense heat, cosmetics, and the like. A nasal discharge is the predisposing cause of sycosis of the upper lip. Shaving with a dull razor is supposed to be the cause in some cases, but those who do not shave are by no means exempt from the disease. Most patients with sycosis are in poor general condition. Men naturally are the most frequent sufferers from the disease.

PATHOLOGY.—Sycosis is primarily a perifolliculitis, the hair follicle and the sebaceous glands being affected secondarily.

DIAGNOSIS.—The two diseases from which sycosis must especially be differentiated are eczema and ringworm of the beard.

Eczema may be limited to the bearded portion of the face, but it is prone to pass over to the non-hairy parts; sycosis is confined to the hairy parts. Eczema is very pruritic and the skin is scratched; sycosis is not pruritic and the skin is not scratched. The lesions of eczema bear no special relation to the hairs; it is a catarrhal disease of the skin, and the hairs are affected as it were accidentally and superficially. No matter how bad an eczema may be, it never destroys the hair. Sycosis is primarily a disease of the hair, the skin between the individual hairs is unaffected except in very bad cases, and the hair may be destroyed. In eczema crusting is a feature of the disease, and when the crusts are removed a raw and oozing surface is exposed. In sycosis the crusts are usually confined to the hair follicles. If diffused crusts are formed, when they are removed it will be found that the hairs stand in little inflammatory areas while the intervening skin does not present a moist surface as is the case in eczema. In some cases it is impossible to make a diagnosis at first, but it is arrived at by studying the effect of treatment, sycosis being more intractable than eczema, and the follicular character becoming more pronounced as the disease approaches recovery.

Ringworm of the beard usually occurs on the chin and neck below the angle of the jaw; sycosis occurs most often on the upper lip and cheeks. Ringworm occurs either as a superficial scaly ring or as large-sized nodules arranged in circles and segments of circles; sycosis occurs as an eruption of papules and pustules pierced by hairs and without any grouping. In ringworm the hairs are broken and split and can be pulled out readily though the root is often left behind; in sycosis the hairs lose their lustre, but otherwise are unaffected, and in the early stages attempts at removing them are very painful. Ringworm once cured does not tend to relapse; sycosis does. Under the microscope the hairs from a case of ringworm will be found loaded with spores and mycelia; in sycosis micro-organisms are found not in the hair but in cultivations from the follicle contents.

Acne should offer no difficulty in diagnosis, as it occurs all over the face and comedones are always present.

PROGNOSIS.—While the disease is essentially chronic, it is curable. Permanent loss of hair is exceptional.

TREATMENT.—When the upper lip is affected it is necessary first to seek out and cure any disease of the mucous membrane of the nose that may be present. In all cases attention to the general health should be given, so as to improve the character of the soil and enable it to resist the invasion of the fungus. The skin must be protected from irritation. The congestion of the skin that is often present in acute cases should be relieved by the administration of laxatives. There is no specific for the disease. Locally, the treatment will vary with the stage of the disease. At the beginning the inflammation may be treated by bathing the affected parts with hot water and following this with an alkaline lotion, such as black wash, lead and opium wash, or a zinc lotion containing two per cent. of salicylic acid. In some cases the application of six drachms of the ointment of the ammoniate of mercury and two drachms of cold cream will abort the disease. When pustules have formed the hairs should be plucked from the diseased follicles,—a conservative process, as it tends to prevent the destruction of the hair papillæ. If there are a large number of pustules a rapidly favorable effect may be produced by going over the face with a dermal curette, after which the parts should be bathed with a 1 to 1,000 solution of bichloride of mercury. If crusts are present they should be removed by soaking them at night with a two-per-cent. solution of salicylic acid in sweet oil, and washing them off on the next day with soap and water. The applications advised above may be used. Diachylon ointment, made according to Hebra's formula and spread on cloths and bound down on the face, is an excellent remedy.

In more chronic conditions sulphur ointment is often a sovereign remedy. The employment of tumenol is at times followed by brilliant results. Tar ointment may be used. In very obstinate cases we may have to resort to stimulation by means of scrubbing with green soap and then binding on zinc-oxide ointment. It is best to keep the beard clipped short during treatment. Epilation is advised by many authorities. Many cases have been cured by both radio- and phototherapy. As the disease is a most obstinate one, we shall have to make many changes in our treatment before we succeed in curing it. It is well to continue some protective applications for several weeks after the disease seems to have been cured.

George Thomas Jackson.

SYMPATHETIC NERVOUS SYSTEM.—An orderly presentation of the facts and theories relating to the sympathetic nervous system calls for the adoption of the following three heads: Anatomy, Histology, and Physiology.

GENERAL SURVEY OF ANATOMY.

The sympathetic nervous system is composed of the following anatomical elements:

1. The great gangliated cords. 2. The intermediate or central nerve plexuses. 3. The peripheral plexuses. 4. The terminal or monocellular ganglia. The general structure and topographical relations of each of these will first be considered, and afterward the general relations of these divisions to each other and to the central nervous system.

I. *The Great Gangliated Cords.*—The great gangliated cords (sympathetic cords, sympathetic nerves; trunci sympathici; Grenzstrang des Sympathicus; nerf grand sympathique) consist of a series of ganglia (sympathetic ganglia, ganglia trunci sympathici) united to each other by longitudinal cords, the so-called *rami internodiales.* These two gangliated cords are placed symmetrically, partly in front and partly to the side of the vertebral column, and extend from the base of the skull to the coccyx. The internal carotid nerve which emanates from the uppermost cervical sympathetic ganglion must be considered the upward continuation of the sympathetic cord into the region of the head. Some of the cephalic ganglia, viz., the ciliary, the sphenopalatine, the otic, the submaxillary, likewise the cervical ganglion of the pneumogastric, and probably also the ganglion petrosum glossopharyngei, must be regarded as homologues of the ganglia of the great sympathetic cords.

The two great gangliated cords and their homologues in the cranial division of the sympathetic have the following connections:

1. *The Interfunicular Cords or Rami* (*Rami Interfuniculares*). These serve to unite the two great gangliated cords and are developed to the greatest extent in the lumbar and sacral portions of the sympathetic nerves.

2. *The Communicating Rami* (*Rami Communicantes*) establish a connection between the sympathetic ganglia and the cerebro-spinal nerves. By these rami communicantes the ganglia of the sympathetic chain are united with the anterior primary divisions of the spinal nerves of their immediate vicinity. There are white and gray rami communicantes, the former consisting mainly of medullated fibres, the latter of pale fibres (Gaskell). The two kinds form either separate branches or are in other instances blended into one cord, composed of a white and a gray part. Having arrived in the spinal nerves, the fibres of the rami communicantes, according to Gaskell, take opposite directions; part of the fibres, contained mainly if not all in the white rami, pass into the spinal cord; the other part, contained chiefly, perhaps exclusively, in the gray rami, assume a centrifugal course, passing with the other fibres of the spinal nerve to the periphery. (See Fig. 4576 and page 581.)

The rami communicantes are represented in the cranial division of the sympathetic system by the so-called roots of the cranial sympathetic ganglia (the sphenopalatine, ciliary, etc.).

3. *The Peripheral Rami* (Hoffman and Rauber) or *Rami Efferentes seu Afferentes.* These are branches proceeding from the gangliated cord to the prevertebral plexuses or vice versa.

We now pass to

II. *The Intermediate or Central Nerve Plexuses of the Sympathetic.*—Here it will be convenient to distinguish, as Thane (Quain's "Anatomy") proposes:

1. *The Large Prevertebral Plexuses.* These are three

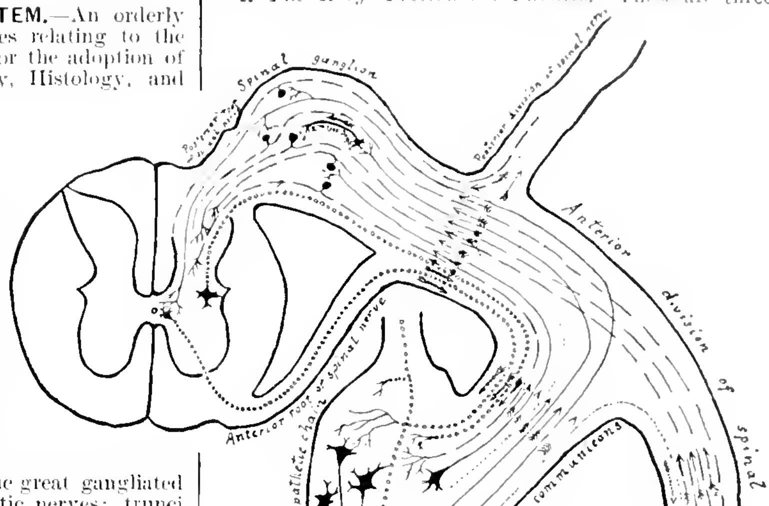

FIG. 4576.—Diagram of the Structural Interrelation between the Cerebro-spinal and Sympathetic Systems.

= Cerebro-spinal neurones of centrifugal functions.

= Cerebro-spinal neurones of centripetal functions.

= Sympathetic neurones of centrifugal functions.

= Sympathetic neurones of centripetal functions.

Marked "2nd type Dogiel" in the figure = the spinal ganglion cell of the second type of Dogiel.

in number, the *cardiac*, the *solar*, and the *hypogastric.* They are not bilateral but single, and lie all in front of the vertebral column, occupying the thorax, abdomen, and pelvis respectively. They are connected on the one hand with its cerebrospinal nerves and with the sympathetic cord, and on the other hand they form centres for the innervation of the viscera.

2. *The Smaller Plexuses of the Sympathetic.* Most of these are in intimate connection with the great prevertebral plexuses, and are in part directly continuous with them, forming, so to say, subdivisions of these. The remainder are united to the prevertebral plexuses by the nerve filaments or cords. These smaller plexuses are also in intimate connection with each other, and probably receive likewise a supply of cerebro spinal fibres. Among these plexuses we may class the *coronary*, the *mesenteric*, the *vesical*, etc.

III. *The Peripheral Plexuses.*—Such plexuses as these are found in the walls of the intestines (Auerbach's and Meissner's), the œsophagus, the bladder, and other hollow viscera. They receive their supply of nerve fibres from the plexuses mentioned under division number two.

IV. *The Terminal Monocellular Ganglia.*—These are the ganglia which Ramon y Cajal has found scattered in the interstices of glandular tissues, within the villi of the intestines, among the interstitial cells of the glands of Lieberkühn, in the substance of the pancreas, in the salivary glands, etc.

THEORIES OF THE GENERAL STRUCTURE OF THE SYMPATHETIC AND ITS CONNECTION WITH THE CEREBRO-SPINAL SYSTEM.—Before passing to a detailed description of the various parts of the sympathetic system, I deem it necessary to give a few general remarks anent the theories of the general structure of the sympathetic and the interrelation of its parts to the central nervous system by fibre tracts. The sympathetic nervous system contains fibres of centripetal, *i.e.*, sensory, and of centrifugal function. The centrifugal function may be motor (viscero-motor or vaso-motor), secretory, trophic, or it may be inhibitory (viscero-inhibitory, vaso-inhibitory, secreto-inhibitory). This division of the centrifugal fibres into centrifugo-exciting and centrifugo inhibiting fibres may hold true also of the centripetal fibres; these are probably also centripeto exciting and centripeto-inhibitory fibres. The centrifugal fibres must further be divided into at least two varieties, which distinguish themselves by their mode of origin.

1. *Cerebro-spinal motor* (or, more correctly, centrifugal) fibres, called also *motor fibres of the first order* by Kölliker, and *preganglionic fibres* by Langley (see Fig. 4576). These fibres have their cells of origin in the spinal cord or cerebral axis, being, in fact, the axis-cylinders of such cells. These fibres condition the dependence of the cells of the sympathetic upon the cerebro-spinal system.

2. *Sympathetic motor* (or in general centrifugal) *fibres*, called also *motor fibres of the second order* (Kölliker) and *post-ganglionic fibres* (Langley) (see Fig. 4576). These have their cells of origin in the ganglia of the sympathetic system, some in the ganglia of the two great gangliated cords, others in the prevertebral or peripheral plexuses. The fibres of the first named order terminate in end-arborizations or pericellular nests around those nerve cells of the sympathetic ganglia or plexuses which give origin to fibres of the second order; in this manner the conduction of a motor impulse to the periphery is possible.

The existence of a third or fourth set of fibres is denied by Langley and Kölliker, but claimed by Jendrassik. The former two deny that the connection of the primary motor centre of the spinal cord or cerebral axis with the periphery is ever established by more than two sets of neurones, which the latter claims.

Jendrassik's ingenious theory of the general structure of the sympathetic cannot be discussed nor quoted in detail here, but must be read in the original (see literary references at the end of this article).

The views of the mode of origin of the sensory fibres of the sympathetic system and of the manner of their connection with the cerebro-spinal system are still divided. Kölliker claims that all sensory fibres of the sympathetic originate from cells of the spinal ganglia in exactly the same manner as do the sensory fibres of the cerebro-spinal system. Dogiel, on the other hand, is inclined to assume the existence of specific sympathetic fibres derived from cells of sympathetic ganglia or plexuses (see Fig. 4576, second type Dogiel). Researches by J. Collins and the writer confirm Dogiel's view.

The two kinds of motor fibres, the cerebro-spinal and the sympathetic, are represented in nearly all subdivisions of the sympathetic system. Both kinds are met with in the rami communicantes, the white rami of which are for the most part composed of cerebro-spinal, the gray ones chiefly of sympathetic fibres (Gaskell). Many efferent rami contain predominantly sympathetic fibres; on the other hand, those efferent rami which proceed from the ganglia of the thoracic part of the sympathetic cord and unite to form the splanchnic nerves are said by Langley to be for the most part cerebro-spinal fibres, showing that they pass through the sympathetic ganglia of the thoracic portion without being interrupted by the cells of the latter. Cerebro spinal fibres are found also in the more peripheral plexuses, intermingled with sympathetic fibres

A word should be said here regarding inhibitory nerves. These may be of the efferent (analogous to motor nerves) or afferent order (analogous to sensory nerves), inasmuch as they can display their inhibitory influence on a given nerve cell in both a descending (toward the centrifugally terminal cells) and an ascending (toward the same cell centripetally) direction. Such inhibitory nerves are of frequent occurrence. Indeed, wherever in the vegetative system one finds nerves performing motor, vaso-motor, or secretory functions, one also finds usually the antagonists, that is, nerves inhibiting such functions. The inhibitory nerves have been encountered again and again by physiologists, and for a long time their rôle was not understood. Gaskell, however, has given a very ingenious and plausible interpretation of their significance. In defining anabolism and catabolism he expresses himself as follows

"There is, then, to my mind, no greater mystery involved in the conception of a nerve of *inhibition* than of a nerve of contraction. In the former case the cessation of function, the relaxation of tissue, is the symptom of constructive chemical changes going on in the tissue, *i.e.*, the anabolism or assimilation or trophic action, in precisely the same way as the activity of function, namely, the contraction of tissue, is a symptom of destructive changes, *i.e.*, catabolism or dissolution." Or, by transcribing this, we may say that the purpose of *inhibition* is the installation of restorative or constructive or anabolic changes in the tissue, while function is the expression of opposite changes, *i.e.*, destructive or catabolic changes. It is evident, however, that the installation of restorative changes after function (or perhaps even during function) is indispensable for the resumption of function. The rôle of inhibition seen in this light clearly gains great importance for the muscular, glandular, and other activities.

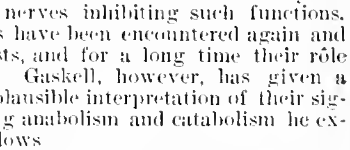

FIG. 4577.—Shows the Neurone *A* under the Exciting Influence of Neurones *B* and *C*. (The direction of the nerve current is indicated thus →.)

The writer (Onuf, "A Tentative Explanation of Some of the Phenomena of Inhibition on a Histophysiological Basis, Including a Hypothesis Regarding the Function of the Pyramidal Tracts," *State Hospitals Bulletin*, 1897) has attempted to give an explanation of inhibition on a histophysiological basis, and has called attention to the regulative rôle that inhibition may have on certain functions. The theory may be expressed in word and diagram (Figs. 4577 and 4578) as follows.

For the excitation of a nerve cell, the nerve current has to pass in the direction from the cell body or its protoplasmatic processes toward the nervous process; for the inhibition of the cell, the nerve current has to pass in the opposite direction, that is, from the nerve process or its collaterals, back to the cell body. In other words, to produce excitation of a given cell, the nerve current must enter this cell from the surface of its cell body or of its dendrites; but in order to inhibit or moderate the action of the cell, the nerve current has to enter the cell from its nerve process or collaterals thereof.

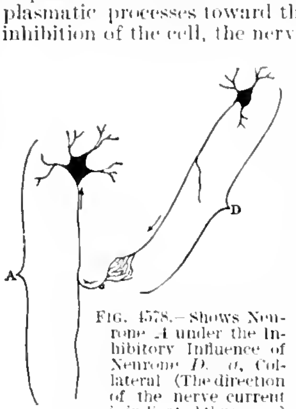

FIG. 4578.—Shows Neurone *A* under the Inhibitory Influence of Neurone *D*. *a*, Collateral. (The direction of the nerve current is indicated thus ⟶.)

These two modes of action are best illustrated by the diagrams (Figs. 4577 and 4578). For both figures the same neurone *A* has been chosen. Fig. 4577 shows this neurone *A* under the influence of excitation from the neurones *B* and *C*. Fig. 4578 represents neurone *A* under the influence of inhibitory action from the neurone *D*.

ANATOMY OF THE GANGLIATED CORDS.

We shall begin the detailed anatomical account with a description of *the two great gangliated cords*.

It is customary to distinguish four parts or portions of the great gangliated cords, the cervical, the thoracic, the lumbar, and the sacral. We shall describe these in this order, basing our description on that given by Thane (Quain's "Anatomy").

I. CERVICAL PART OF THE GANGLIATED CORD.—This is situated behind the great blood-vessels of the neck, resting on the muscles which cover the anterior surface of the vertebral column. The cervical part of the gangliated cord consists of three ganglia, as described below.

1. *Upper or Superior Cervical Ganglion.*—This, the largest ganglion in the great sympathetic cord, lies on the rectus anticus major muscle, opposite the second and third cervical vertebræ, behind the internal carotid artery, and to the inner side of the pneumogastric nerve. Usually fusiform in shape, it continues above into an ascending branch and tapers below into the connective cord. The following are the connections of this ganglion:

(*a*) *Connection with Spinal Nerves.* At its outer side the superior cervical ganglion is connected with the first four spinal nerves by means of gray rami communicantes. The branches to the third and fourth cervical nerves often pierce the rectus anticus major muscle. They may be given off from the upper part of the cord instead of directly from the ganglion. It probably consists primarily of several ganglia which have coalesced. Gaskell considers it to be a distal or collateral ganglion. It receives its cerebro-spinal fibres, which constitute the "cervical splanchnic nerve" of Gaskell, from the upper dorsal nerves to the cervical part of the sympathetic cord.

(*b*) *Connection with Cranial Nerves.* The ganglion or its cranial continuation is connected by small branches with the lower ganglion of the pneumogastric (ganglion cervicale vagi, plexus nodosus), and with the twelfth cranial nerve near the base of the skull. Another branch (N. jugularis), which is ascending, divides at the base of the skull into filaments, one of which ends in the petrosal ganglion of the glosso-pharyngeal nerve, while the others enter the jugular foramen to join the ganglion of the root of the pneumogastric.

Besides the branches connecting it with the cranial and spinal nerves, the first cervical ganglion gives off other ascending branches, viz., pharyngeal branches, the upper carotid nerve, and branches to the blood vessels, as well as two or three filaments which pierce the prevertebral muscles to supply the upper cervical vertebræ and their ligaments.

(*c*) *Ascending Branch and Cranial Plexuses.* The ascending or carotid branch of the first ganglion (N. caroticus internus) is in some degree a prolongation of the ganglion itself. Ascending behind the internal carotid artery, it enters the carotid canal, dividing here into an external and internal division.

The *external division*, lying on the outer side of the internal carotid artery, distributes filaments to the latter, receives one or two carotico-tympanic twigs from the tympanic branch of the glosso-pharyngeal, and after communicating by means of other filaments with the internal division of the cord forms the carotid plexus.

The *internal division*, rather the smaller of the two and situated on the inner side of the internal carotid, supplies filaments to the carotid artery and goes to form the cavernous plexus. The terminal parts of these divisions of the cranial cord are prolonged on the trunk of the internal carotid and extend to the cerebral and ophthalmic arteries, around which they form secondary plexuses, those on the cerebral arteries ascending on the pia mater. One minute plexus enters the eyeball, accompanying the central artery of the retina.

The *carotid plexus* (plexus caroticus internus) is situated on the outer side of the internal carotid artery at its sec-

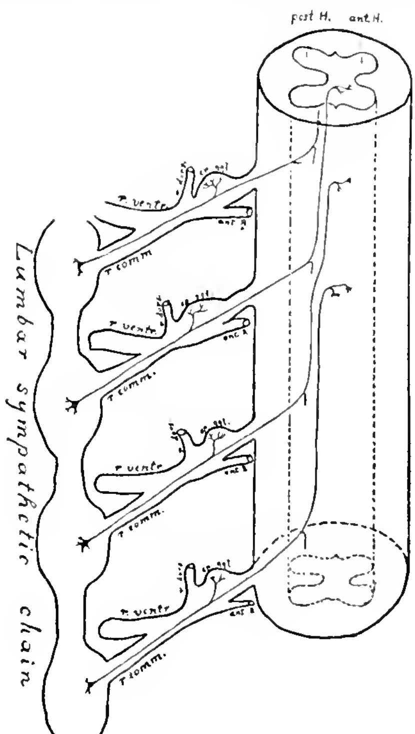

FIG. 4579.—Diagram to show the Ascent in the Spinal Cord of the Afferent (and probable Descent of the Efferent) Fibres derived from the Lumbar Sympathetic Chain, as resulting from the degenerations following removal of lumbar sympathetic ganglia. *post. For further details see p. 590.

ond bend (reckoning from below) or between the second and third bends. It forms connection with the sixth nerve and with the Gasserian ganglion (the latter, however, occasionally receiving its supply from the cavernous plexus) gives off the large deep petrosal nerve, which together with the large superficial petrosal from the facial forms the Vidian nerve, and so joins the sphenopalatine ganglion. It further gives off the small deep petrosal nerve to the tympanic plexus, and supplies filaments to the internal carotid artery.

Cavernous Plexus.—This plexus, taking its name from its position in the cavernous sinus, is placed below and slightly to the inner side of the highest turn of the internal carotid artery. Besides giving branches to the artery and all its branches, *i.e.*, the ophthalmic, the anterior cerebral, the median cerebral, and the posterior communicating arteries, and to the walls of the sinus, it communicates with the third, fourth, and the ophthalmic divisions of the fifth cranial nerve. The latter connection supplies filaments to the ophthalmic trunk (inner side) of the fifth nerve, and the sympathetic root to the ciliary ganglion. The cavernous plexus also furnishes minute filaments to the pituitary body.

(*d*) *Pharyngeal Nerves and Plexus.* The pharyngeal nerves, originating from the forepart of the first cervical ganglion, pass to the side of the pharynx. They unite with branches of the pneumogastric and glossopharyngeal nerves, forming the pharyngeal plexus. The latter supplies the muscles and mucous membrane of the pharynx, and connects with the superior and external laryngeal nerves.

(*e*) *Laryngeal Branches.* These branches anastomose with twigs from the inferior laryngeal to form the so-called laryngeal plexus.

(*f*) *Branches to Blood-Vessels.* The superior cervical ganglion gives off the external carotid nerves, which, twining around the external carotid artery, form the plexus caroticus externus. This plexus is continued on the branches of the said artery. The fine plexuses then formed are named after the respective arteries. The plexus on the facial artery supplies a filament forming the sympathetic root of the submaxillary ganglion. The plexus on the middle meningeal artery connects with the otic ganglion and with the geniculate ganglion of the facial (external superficial petrosal nerve). One branch is given off to the parotid gland. Besides microscopical ganglia found in the vascular plexuses, several larger ones are more constantly met with, for instance, the temporal ganglion.

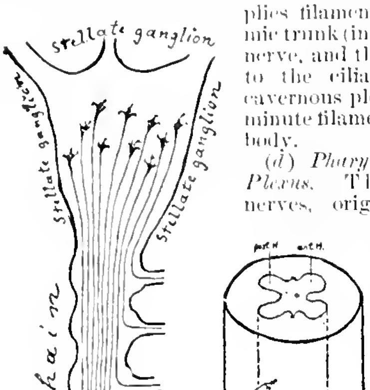

FIG. 4580.—Diagram showing the Afferent Fibres Derived from the Stellate Ganglion and Lower Thoracic Sympathetic Chain in their Course to the Spinal Cord. The course is suggested by the degenerations following removal of the stellate ganglion and also the lower thoracic sympathetic chain. The efferent fibres very likely have a similar course in opposite direction. *post.H.*, Posterior horn; *ant.H.*, anterior horn; *r. ventr.*, ramus ventralis (anterior division) of dorsal nerve; *r. dors.*, ramus dorsalis (posterior division) of dorsal nerve; *ant.R.*, anterior root; *r. comm.*, ramus communicans.

For further details see p. 590.

(*g*) *Upper* (*or Superficial*) *Cardiac Nerve.* This nerve, together with the middle and inferior cardiac nerves, goes to form the cardiac plexus. The left and the right nerves differ somewhat in their disposition, but in its course on the neck the right upper cardiac nerve has relatively the same position and relations as the left one, being placed in the back of the carotid sheath.

2. *Middle Cervical Ganglion.*—This ganglion is situated about opposite the sixth or seventh cervical vertebra. It is the smallest of the cervical ganglia. Gray branches unite it with the fifth and sixth cervical spinal nerves and with the superior and inferior cervical ganglia. It gives off thyroid branches, which form the inferior thyroid plexus and the middle cardiac nerve. The latter, in its course to the cardiac plexus, gives off filaments to the recurrent branch of the pneumogastric, to the upper cardiac nerve, and to the thyroid branches of the middle cervical ganglion.

3. *Lower or Inferior Cervical Ganglion.*—This ganglion is frequently united to the first thoracic ganglion, and the common mass is then designated as the first thoracic ganglion. Its shape is irregular, flattened. The ganglion is placed over the first costo-vertebral articulation in the lateral angle between the subclavian and vertebral arteries. Its union with the middle cervical ganglion is usually formed by a cord passing behind the vertebral artery, sometimes, however, especially on the left side, by a ring around the vessel. The two ganglia are also united by the ansa subclavia (ansa Vieussenii). The latter either passes as a single cord between the middle cervical and the lower cervical or first dorsal ganglion in front of the subclavian artery, or it forms a loop around that vessel, supplying it with small offshoots (plexus subclavius), which give off filaments to the internal mammary artery, communicating in some cases with the phrenic nerve.

The inferior cervical ganglion sends gray communicating branches to the lowest two cervical nerves, gives off the lower cardiac nerve (which passes behind the brachiocephalic artery on the right and behind the transverse aorta on the left side), and supplies twigs to the blood-vessels. The latter ascend along the vertebral artery, forming the vertebral plexus, the ultimate ramifications of which are continued on the intracranial branches of the vertebral and basilar arteries.

II. THORACIC PART OF THE GANGLIATED CORD.—The ganglia of the thoracic sympathetic are usually eleven in number, seldom twelve. The two thoracic sympathetic cords lie on either side of the spinal column over the costovertebral articulation, covered by the pleura, the third to the eleventh ganglia being generally placed over the heads of the ribs, the first one in the first intercostal space and the last one a little in front of the head of the twelfth rib. The first ganglion is often amalgamated with the lower cervical ganglion.

1. *Rami Communicantes.*—The branches connecting the thoracic sympathetic ganglia with the anterior divisions (rami ventrales) of the dorsal nerves are usually two in number for each ganglion, one of these being white and the other gray.

2. *Interfunicular Rami.*—Branches establishing a connection of the two thoracic sympathetic cords between each other are often found, but their occurrence is not constant.

3. *Peripheral Branches of the Ganglia.*—The upper four or five ganglia send small branches to the vertebræ and ligaments and to the descending thoracic aorta, on which latter, by union of the branches from the ganglion with filaments from the great splanchnic nerve, they form the plexus aorticus thoracalis. The second, third, and fourth ganglia also supply branches to the posterior pulmonary plexus, formed otherwise chiefly by ramifications of the pneumogastric nerve.

The rami proceeding from the lower six or seven ganglia join to form three cords on either side, known as the great, the small, and the smallest splanchnic nerves (abdominal splanchnics of Gaskell), which pass into the plexuses of the abdomen.

4. *The Great Splanchnic Nerve.*—The roots uniting to form this nerve are those furnished by the fifth or sixth thoracic ganglion and all the succeeding ganglia to the

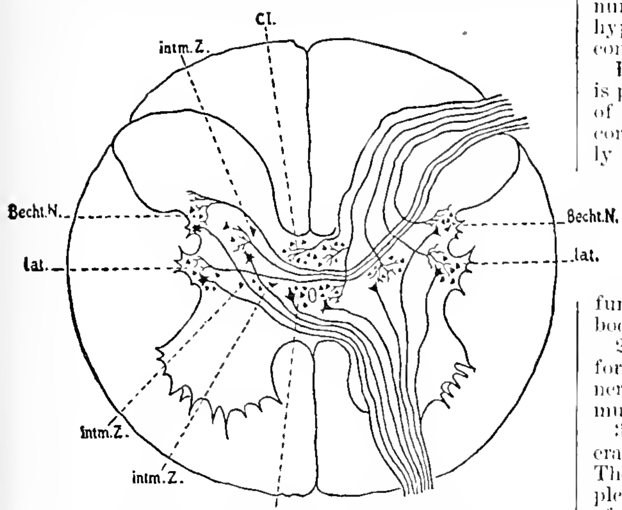

FIG. 4581.—Diagram Illustrating the Spinal Representation or Localization of the Sympathetic Nerve as made very probable from the Degenerations following lesions of the sympathetic chain. *Cl*, Clarke's column; *intm.Z.*, intermediate zone; *Becht.N.*, Bechterew's nucleus; *lat.*, lateral horn group; *parc.*, paracentral group.
See also p. 590.

ninth or tenth (inclusive). The nerve descends over the bodies of the dorsal vertebræ, passing mesiad of the gangliated cord, and, after perforating the crest of the diaphragm, terminates in the upper part of the semilunar ganglion, and sometimes, with a few fibres, in the suprarenal body and the renal plexus. The nerve contains a large part of medullated cerebro-spinal fibres, which give it a white color. They may be traced upward from the highest root along the sympathetic cord as far as the third thoracic ganglion or nerve, or even higher. The great splanchnic nerve often forms a plexus with the small splanchnic nerve, having in many cases a small ganglion (splanchnic ganglion) in its course. The greater splanchnic nerve and the splanchnic ganglion supply the vertebræ and the aorta with filaments.

5. *The Small Splanchnic Nerve.*—The thoracic ganglia giving origin to this nerve are the ninth and tenth, or sometimes the tenth and eleventh. It perforates the diaphragm with or somewhat behind and to the right of the great splanchnic, terminating in the lower part of the semilunar or occasionally in the aortico-renal ganglion. In the thorax anastomoses with the smallest splanchnic are often present.

6. *The Smallest Splanchnic Nerve* (N. renalis posterior of Walter) takes its origin from the last thoracic ganglion and communicates sometimes with the small splanchnic. It pierces the diaphragm with the cord of the sympathetic, and ends in the renal plexus. It is frequently absent as a separate individual nerve, being in this case represented by a branch of the small splanchnic.

The three splanchnic nerves are composed for the most part of cerebro-spinal fibres.

III. Lumbar Part of the Gangliated Cord.—The two lumbar sympathetic cords lie in rather close proximity to each other on the bodies of the lumbar vertebræ, along the inner border of the psoas muscle. Their position is extraperitoneal, the right one being partly covered by the vena cava, the left one by the aorta. Each lumbar cord contains usually four ganglia, but sometimes only three or even only two.

1. *Rami Communicantes.*—As a rule, each of the ganglia of the lumbar sympathetic has two rami communicantes, which, however, are not always connected with the same spinal nerves.

Vol. VII.—37

2. *Rami Interfuniculares.*—These are also inconstant in their occurrence, although more constant than in the thoracic part of the gangliated cords.

3. *Peripheral Branches.*—These branches, varying in number, are distributed to the plexus on the aorta, to the hypogastric plexus, and to the vertebræ and ligaments connecting the latter.

IV. Sacral Part of the Gangliated Cord.—This is placed in front of the sacral bone along the inner side of the foramina sacralia, the two sacral cords converging correspondingly toward the coccyx. Each cord has usually four ganglia, but quite frequently less. Only few branches are given off to the viscera.

1. *Rami Interfuniculares.*—Fine branches uniting the two cords are of constant occurrence here, especially at the lower end, where they form a loop in which a single median ganglion, ganglion impar, or coccygeal ganglion, is often found. The interfunicular rami send off fine filaments into the vertebral bodies, to the coccyx and the coccygeal gland.

2. *Rami Communicantes.*—These are short, often two for one ganglion, frequently united to different sacral nerves. The last or coccygeal ganglion sends a communicating branch to the coccygeal nerve.

3. *Peripheral Branches.*—Only small and few peripheral branches are given off from the sacral ganglia. They are distributed to the sacral bone, to the pelvic plexus, and to the middle sacral artery, on which some of them form a plexus.

The Anatomy of the Plexuses.

I. Cardiac Plexus.—This plexus lies against the transverse aorta and pulmonary artery where these vessels are in contact. It is supplied by the cardiac branches from the cervical ganglia and by those of the pneumogastric nerves. It gives origin to nerves distributed to the heart and to others participating in the inner-

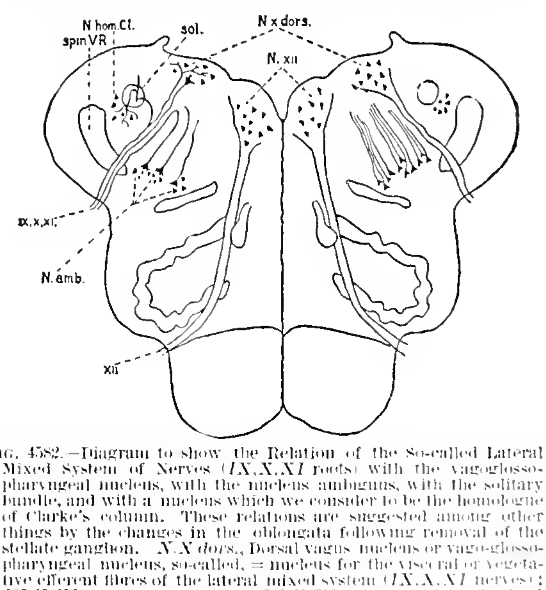

FIG. 4582.—Diagram to show the Relation of the So-called Lateral Mixed System of Nerves (*IX,X,XI* roots) with the vagoglossopharyngeal nucleus, with the nucleus ambiguus, with the solitary bundle, and with a nucleus which we consider to be the homologue of Clarke's column. These relations are suggested among other things by the changes in the oblongata following removal of the stellate ganglion. *N.X dors.*, Dorsal vagus nucleus or vago-glossopharyngeal nucleus, so-called, = nucleus for the visceral or vegetative efferent fibres of the lateral mixed system (*IX,X,XI* nerves); *IX,X,XI* common root of the *IX,X,XI* nerves (= lateral mixed system); *N.amb.*, nucleus ambiguus = nucleus for the somatic efferent fibres of the lateral mixed system (*IX,X,XI* nerves); *sol*, solitary bundle, called also trineural fascicle or descending root of the lateral mixed system; *N.hom.Cl.*, nucleus homologue of Clarke's column; *N.XII*, hypoglossal nucleus; *XII*, hypoglossal nerve; *spin.V.R.*, spinal trigeminal root.
See also p. 590.

vation of the lungs. That part of the cardiac plexus which is situated chiefly behind the vessels is called the deep cardiac plexus, while the one that lies more in front bears the name of superficial cardiac plexus. They are closely connected with each other and give off:

1. The right or posterior coronary plexus, accompanying the right coronary artery.

2. The left or anterior coronary plexus, accompanying the left coronary artery.

Filaments of these latter plexuses ramify under the pericardium.

Microscopical ganglia, which might perhaps be classed among the peripheral plexuses (homologues of Auerbach's and Meissner's plexuses in the wall of the intestine) (see the second foot-note on p. 581), occur in the nerves of the auricles and in the course of the coronary plexuses. The ramifications of the latter give rise also to the terminal plexuses which Gerlach has described as the "Grundplexus," and which, according to the recent investigations of von Openchowski, give off terminal fibres to the muscular fibres. Van Gehuchten has observed, by employment of the method of Golgi in the nerves of the heart of new-born white mice, a very abundant interlacing network between the nerve fibres of the muscle cells of the ventricle walls, but he has not been able to follow fibres of the peripheral ganglia. This same richness of fibres in every portion of the myocardium has been observed by Hymann and Demoor. The myocardial nerve filaments have also been beautifully demonstrated in the frog's heart by Strong.

II. Solar or Epigastric Plexus.—This plexus lies in front of the aorta and of the pillars of the diaphragm, between the right and left suprarenal bodies, and surrounding the origin of the cœliac and superior mesenteric arteries. It is the largest one of the three prevertebral plexuses, being supplied by the large and small splanchnic nerves and some branches of the pneumogastric. From the solar plexus smaller plexuses branch off, accompanying the principal visceral arteries of the abdomen, and thus forming the diaphragmatic, cœliac, mesenteric, and other plexuses.

1. *Semilunar Ganglia* (*Solar Ganglia, Cœliac Ganglia, Abdominal Brain*).—The two principal ganglionic masses of the solar plexus are the left and right semilunar ganglia, which are situated in the interstice between the suprarenal bodies, being connected with each other by a ganglionic and fibre lacework twining around the origin of the cœliac and superior mesenteric arteries.

The lower part of these ganglia, usually detached from the remainder, is known as the aortico-renal ganglion, in which the small splanchnic nerve terminates, and which supplies the greater part of the renal plexus. Another part, lying below and to the right of the origin of the superior mesenteric artery, is named the *superior mesenteric ganglion*. The formation of the following plexuses is contributed to by the solar and other plexuses and by branches of the cerebro-spinal nerves.

2. *Diaphragmatic or Phrenic Plexus.*—This is situated along the arteries at the lower surface of the diaphragm and is derived from the upper part of the semilunar ganglion. It is also supplied by the phrenic nerves. On the right side this plexus contains a ganglion which marks the junction of the phrenic (cerebro-spinal) and the sympathetic fibres. It gives filaments to the diaphragm, to the vena cava, to the suprarenal body, and to the hepatic plexus.

3. *Suprarenal Plexus.*—The nerves to this plexus emanate from the solar plexus, chiefly from the outer part of the semilunar ganglion, but the plexus also receives some filaments from the diaphragmatic plexus and from one of the splanchnic nerves. It is beset with minute ganglia.

4. *Renal Plexus.*—The chief supply of this plexus is from the aortico-renal ganglion, but the solar and aortic plexuses, the smallest splanchnic nerve, and sometimes the small splanchnic nerve, as well as the first lumbar ganglion, furnish also filaments. Ganglia of different sizes (renal ganglia) are met here. The plexuses of both sides give off twigs to the spermatic plexus and a filament to the urethra. The plexus of the right side supplies some filaments to the vena cava.

5. *Spermatic Plexus.*—This is derived for the most part from the renal plexus, and receives in addition some filaments from the aortic plexus. In the male it follows the spermatic artery and supplies the testis, a small spermatic ganglion being frequently found in its course. In the female it accompanies the ovarian artery and is distributed to the ovary and uterus.

6. *Cœliac Plexus.*—This large plexus, derived from the solar and situated in a kind of fenestrated sheath, surrounds the cœliac artery. It subdivides with the artery into stomachic, hepatic, and splenic plexuses, which, following the respective blood-vessels, supply the stomach (coronary and pyloric plexuses), the liver (hepatic plexus), the gall bladder (cystic plexus, derived from the hepatic), the pancreas and duodenum (pancreatico-duodenal plexus, also chiefly from the hepatic), and the spleen (plexus splenicus, or lienalis). These plexuses anastomose with each other, with the mesenteric nerves, and with the suprarenal plexus. All of them receive additional supply from the pneumogastric nerve.

7. *Superior Mesenteric Plexus.*—This plexus is derived chiefly from the lower part of the solar plexus and from the superior mesenteric ganglion, receiving also fibres from the right pneumogastric at its junction with the cœliac plexus. Following the course and distribution of the superior mesenteric artery, this plexus divides into subplexuses named after the respective vessels, which subplexuses finally pass upon the intestine along the line of attachment of the mesentery. A large number of the filaments terminate between the two layers of the mesentery in so-called Pacinian corpuscles. These are cerebrospinal fibres. In the wall of the intestine the peripheral plexuses (Auerbach's and Meissner's) are formed.

8. *Aortic Plexus.*—The aortic or intermesenteric plexus (plexus aorticus abdominalis) is arranged along the abdominal aorta between the origin of the superior and that of the inferior mesenteric artery, mostly in the form of two lateral cords, which are connected above with the semilunar ganglia and renal plexuses, and in front with each other by communicating branches passing in front of the aorta. The plexus is also supplied from some of the lumbar ganglia. It continues on the inferior mesenteric artery to form the inferior mesenteric plexus. The latter is connected with the inferior mesenteric ganglion, placed below the origin of the artery. The aortic plexus furnishes also part of the spermatic plexus. It gives some filaments to the inferior vena cava, and ends below in the hypogastric plexus.

9. *Inferior Mesenteric Plexus.*—This plexus, springing mainly from the left lateral part of the aortic plexus, clusters around the inferior mesenteric artery. It supplies the left or descending and the sigmoid colon, and the rectum. Its colonic branches anastomose with the middle colonic branches of the superior mesenteric plexus. Other branches connect in the pelvis with the pelvic plexus.

III. Hypogastric Plexus.—The hypogastric plexus, destined for the supply of the viscera of the pelvis, is a flat plexiform mass situated in front of the lowest lumbar vertebra, between the two common iliac arteries. It is the downward continuation of the two cords which form the aortic plexus, and it receives a considerable supply of branches from the lumbar ganglia. Below, it bifurcates to form the pelvic or inferior hypogastric plexuses.

The *inferior hypogastric or pelvic plexuses*, one on each side, are derived from the hypogastric plexus. They lie by the side of the rectum, and of the vagina in the female. After descending a short distance, they receive branches from spinal nerves, namely, the third and fourth and sometimes the second sacral, and from the sacral ganglion of the sympathetic.

The plexus ramifies with and along the branches of the internal iliac artery, forming the hemorrhoidal and vesical nerves which are common to both sexes, and other nerves or plexuses special to each, viz., in the male, for the prostate, vesiculæ seminales, and vas deferens; in the female, for the vagina, uterus, ovaries, and Fallopian tubes. Accordingly, the following plexuses can be distinguished:

1. *Hemorrhoidal Plexus.*—Originating from the upper part of the pelvic plexus, this plexus anastomoses with the nerves (superior hemorrhoidal) which descend with the inferior mesenteric artery and penetrate the coats of the rectum.

2. *Vesical Plexus.*—The nerve plexuses of the bladder are continued from the lower part of the pelvic plexus and are placed chiefly on the lower surface of the bladder. Besides supplying the latter, they furnish nerves to the vas deferens and to the seminal vesicle.

3. *Prostatic Plexus.*—Situated between the prostate gland and the levator ani, this plexus supplies the prostate and the seminal vesicle in the form of the nervi cavernosi or erigentes. It is then continued forward to supply the erectile substance of the penis.

4. *Vaginal Nerves.*—These nerves, derived from the lower part of the pelvic plexus, proceed directly to the vagina.

5. *Nerves of the Uterus.*—According to Foote and Chapman, from whom the description here following is taken,* the uterus has a double nerve supply, namely, from the uterine and from the ovarian plexus. The uterine plexus, they find, is formed by the union of the hypogastric plexus with the sacral sympathetic cord. At this point of union there is a cluster of small ganglia called the ganglion cervicale of Frankenhäuser, situated upon either side of the cervix just at its junction with the vaginal wall. From this point the plexus spreads out fan-like, following and encircling the branches of the internal iliac artery. It distributes its branches to the uterus, vagina, rectum, bladder, ureter, broad ligaments, and pelvic fascia. The branches to the uterus are few in number and supply the lower uterine segments, being composed mainly of fibres from the third sacral nerves. Thus far no fibres from the uterine plexus have been found to enter the uterus above the internal os, unless some of its branches, passing to the broad ligaments, enter the uterus after uniting with the branches of the ovarian plexus. As yet this is undetermined.

The uterine plexus receives its connections with the spinal cord from the third sacral nerve, with some branches from the fourth, and at times from the second. The hypogastric portion of the plexus also has spinal connections through the rami communicantes of the first and second lumbar ganglia of the sympathetic.

The ovarian plexus is derived from the renal plexus and the upper aortic. These plexuses derive their fibres from the solar plexus upon the left side, and from the solar and hepatic plexuses on the right. The connections passing from the plexus to the central nervous system are along the following paths: 1. Through the rami communicantes of the lower dorsal nerves. 2. The greater and lesser splanchnics. 3. The pneumogastric.

The ovarian plexus receives its filaments from the vagus through the renal plexus, from which it is probably derived. The uterine plexus has merely a spinal connection.

Chapman and Foote conclude that of the two plexuses described the ovarian is the controlling nerve supply to the ovary, tube, and uterus, and the path along which are conveyed the most important stimuli passing to these organs.

HISTOLOGY.

In discussing the histology of the sympathetic nervous system, it has been found convenient to divide the structures of the same into two groups, namely, first, the components of the sympathetic chain; second, the components of the nerve plexuses of the sympathetic and of the terminal monocellular ganglia.

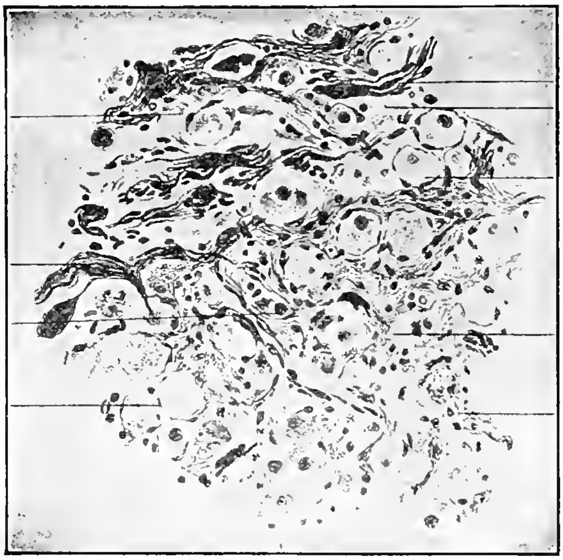

FIG. 4583.—Section of Stellate Ganglion of a Normal Young Cat. Double stain (carm., Pal.); *cps*, pericellular capsula with nuclei; *med*, medullated fibres; *non*, non-medullated fibres.

Histology of the Cords and Ganglia. — The nerves of the sympathetic nervous system are of variable appearance, white, gray, or grayish. The white contain proportionately a large amount of fine, white, medullated fibres; the gray a comparatively slight amount. In some parts of the sympathetic nerves the white and gray fibres run along for a considerable distance without blending, but usually after the white fasciculi have passed through one or more ganglia, the two sets of fibres become thoroughly mixed. The white fibres are about one-half the size of the gray, and measure from 2.5 μ to 3.3 μ in diameter. Most of them belong to the cerebro-spinal, but part of them to the sympathetic system; at least the investigations of Huber and Dogiel speak in favor of fibres of the latter kind. Besides the fine medullated fibres, coarse ones are met with in smaller number. These Roux has proved to be for the most part, if not all, cerebro-spinal sensory fibres.

The type of cells entering into the constitution of the sympathetic ganglia forms a very important distinction between mammalia and fishes and other vertebrates; it also furnishes a point of distinction between the sympathetic and spinal ganglia in each class. In the mammalia the cells are multipolar; in the fishes and amphibia they are unipolar and bipolar. Retzius has used this fact to great advantage in allotting certain ganglia of the cephalic extremity, previously regarded as belonging to the cerebro-spinal nerves, to their proper class.

The ganglia themselves are surrounded by a thin, firm, adherent covering of connective tissue, which sends prolongations through the ganglion and divides it into compartments of different sizes and shapes. The individuality of these compartments is obscured by the fibre constituents of the ganglion. The nerve cells of the ganglion are surrounded by a pericellular capsule (Fig. 4583, *cps*), a membrane in which nuclei are embedded at definite intervals. It is taught by some histologists (Schultze) that this transparent capsule is continuous with the primitive sheaths of the nerve fibres. On careful examination it is seen to consist of flat epithelial like cells, and contains a certain amount of connective tissue, probably the same as that entering into the formation of the compartments of the ganglion. In Fig. 4583, which

* The writer is indebted to these authors for a private communication of their results, part of which has not been published yet, while in part they have appeared in the form of a preliminary communication in the Brooklyn Medical Journal, December, 1901.

illustrates a piece of the stellate ganglion of a young cat (double stain: carmine, Pal.), the medullated fibres (*med*) appear as heavy black strands; the non-medullated (*non*) as reddish-brown fibres. The bundles of medullated fibres go predominantly toward the middle of the ganglion, where they undergo brush-like division. In the centre of the ganglion are seen bundles of medullated and non-medullated fibres, while toward the periphery the fibres are almost exclusively of the latter variety (fibres of Remak). Delicate bundles of these non-medullated fibres are seen passing between the constituent cells of the ganglia, particularly toward the periphery.

Fig. 4584 represents part of a sympathetic ganglion, showing the cells as they are brought out with Nissl's method of staining (methylene blue). The cells have usually one nucleus, but Huber and Bruckner observed

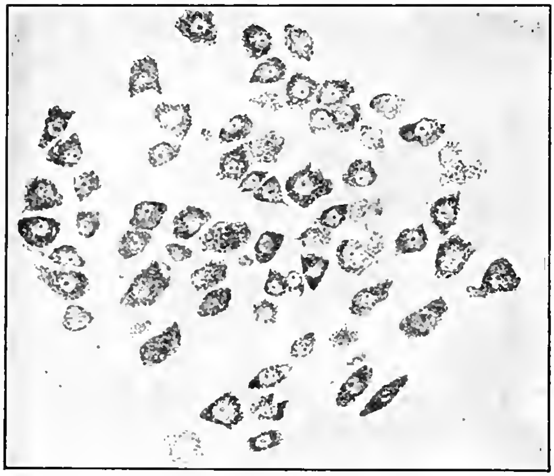

FIG. 4584.—Cells from a Part of a Sympathetic Ganglion.

cells with two nuclei, and Bruckner quotes Professor Obregia as having seen numerous cells with two nuclei make their appearance after electrical excitation. Some cells then also showed partial and others complete division. An endocellular network, apparently of the same nature as Golgi found it in the cells of the intervertebral ganglia, was observed by Veratti in the cells of the cervical ganglia of the sympathetic.

Besides nerve cells, Stilling has discovered in the sympathetic ganglia large polygonal cells, staining deeply in chromic acid and found also in the suprarenal capsules.

Each nerve cell has many protoplasmic processes of longer or shorter course that terminate not far distant from the cells of their origin, and a nervous process (axone) which goes to form a constituent of a peripheral ramus, of a ramus intermedialis, or of a ramus communicans.

The variation in form and extent of the dendritic processes of the multipolar cells of the sympathetic ganglia, as seen with Golgi's method, is considerable. In some dendrites the terminal ramifications are very numerous and cluster in the shape of a basket, forming a pericellular network around other cells. This network, however, does not come in contact with the cell bodies, but lies around the capsule of the cells (Huber). Ramon y Cajal is inclined to the belief that these clusters are of great significance in explaining the functional interrelationship of the cells, a belief which is not shared by von Kölliker and van Gehuchten. Others terminate very simply and free, each one of the dendrites having a number of nodes or varicosities developed upon it. When the protoplasmic processes terminate freely among the cells of the ganglion, their ulterior ramifications are very fine and it is difficult to distinguish them from the termination in the ganglion of the nerve fibres that enter and end there.

Dogiel assumes that all cells of a ganglion are associated by means of a network formed by the dendritic processes. Some of these processes reach even into the next ganglion.

Nerve Fibres of the Ganglia of the Sympathetic Chain and Their Connections.—The nerve fibres in a sympathetic ganglion may be enumerated as:

1. Fibres of passage.
2. Fibres originating from cells of the ganglion.
3. Terminal fibres from other sources.

The ganglion may also contain collaterals from communicating rami or commissural fibres, and probably from peripheral rami, if we assume that fibres arise from cells of the peripheral sympathetic ganglia.

Most nerve fibres in passing through a sympathetic ganglion give off collateral branches, which terminate by free ramifications between and around the cells which enter into the constitution of the ganglion. In every ganglion of the sympathetic chain there are found a number of fibres that terminate there. These may be longitudinal fibres belonging to the sympathetic chain, or peripheral (centripetal) fibres arising from nerve cells of peripheral ganglia and cerebro-spinal fibres conducted by the communicans ramus (see Fig. 4576). Many of those fibres which are continued as pale fibres lose their medullary sheaths on joining with the cells of the ganglia; others pass through the proximate ganglion without relationship to the nerve cells (*fibres de passage*, see Fig. 4576), and are continued toward the peripheral distribution as fine medullated fibres; but even these lose their sheaths in passing through the distal ganglia of the sympathetic system. All these terminal and lateral ramifications produce in the substance of each ganglion a most intricate interlacement of nerve fibrillæ enveloping the protoplasmatic prolongations and the bodies of the cells which make up the real ganglionic mass.

Fibres that come from the roots of the spinal nerves end in arborizations within the sympathetic ganglia. According to Ramon y Cajal, they form definite pericellular networks (not confirmed by Lenhossek), which Huber finds to be always intracapsular, *i.e.*, situated within the capsule of the cell. Directly before reaching the cell around which they terminate, many of these fibres describe a number of spiral turns around the neuraxon of such cell (Huber). These fibres that pass in from the spinal roots are some of them unquestionably motor (see Fig. 4576), and take their origin, according to Kölliker, from cells of the spinal cord (denied by Dogiel).

Sala describes two types of fibres in a ganglion: (1) The varicose fibres, so called because of the tortuosity in parts of their course; and (2) the dividing fibres, found chiefly in the periphery of the ganglion. The varicose fibres are probably identical with Remak's fibres. They remain undivided. Many of them take their origin from the cells of the ganglion within which they are seen, while others take their origin in adjoining ganglia (fibres of passage), without entering into any connection with it, as they do not give off collaterals. The dividing fibres send off collaterals, the ramifications of which constitute the diffuse network of the ganglion. Sala believed that the varicose, undivided fibres are the real sympathetic fibres, *i.e.*, that they originate from cells of the sympathetic ganglia, while the dividing fibres are in reality from the cerebro-spinal system.

Langley's conclusions: According to Langley, who based his conclusions upon the nicotine experiments (quoted in the foot-note on p. 587), all the cerebro-spinal motor fibres that enter into the sympathetic nervous system terminate in one or another sympathetic ganglion by establishing connection with the constituent cells of the ganglion. The axis-cylinder prolongations of the centrifugal sympathetic fibres terminate in the muscular walls of the blood-vessels, in the viscera, or in the glands. The sympathetic ganglia are in reality the ending-place of one set of neurones and the place of origin of a second set. Each ganglion of the sympathetic trunk is to be regarded as a primary centre apart from any connections with the spinal cord. The fibres which it sends off run in the main to the corresponding spinal nerve and follow the course of this nerve. These fibres, emerging from the ganglion as a primary centre, are connected with all the peripheral structures with which sympathetic fibres can be connected and which lie in their course, so that the function of the nerve fibres is determined by the structures in which they terminate and not by the nature of the nerve fibres. A nerve fibre proceeding from a sympathetic cell has no other sympathetic cell in its course (the cells of Meissner and Auerbach's plexuses are not considered by Langley to be types of sympathetic nerve cells). The fibres from the spinal cord to the sympathetic ganglion connect certain cells of the spinal cord with the cells of the spinal ganglia in the same way as the fibres of the pyramidal tract connect certain cells of the brain with the cells of the spinal cord. These spinal fibres become pilo-motor, vaso motor, secretory, according as the fibres from the sympathetic with which they are connected end within the erector muscles of the hair, the muscles of the blood-vessels, or within the glands.

The medullary fibres of the ciliary ganglion have been traced by Kölliker immediately into the eyeball through the ciliary nerve into the sphincter of the iris, ending in the ciliary body.

THE MORPHOLOGICAL ORGANIZATION OF THE VARIOUS RAMI.—I. Rami internodiales.

II. Rami communicantes.

III. Rami peripherales.

I. *The Rami Internodiales* (see Fig. 4576, ramus internodialis).—The fibres that are to be seen passing longitudinally from a ganglion into a ramus internodialis are the axis-cylinder prolongations of nerve cells situated in the same ganglion or in an adjacent ganglion. In other words, these rami internodiales or interganglionic longitudinal strands of the sympathetic are made up of vertical commissural fibres, coursing longitudinally through superimposed ganglia.

II. *The Rami Communicantes.*—The rami communicantes are connected with the so-called *anterior division* or ramus ventralis of the cerebro-spinal nerves to which they are joined. In a ramus communicans two classes of fibres, namely, fibres conducting toward the ganglion and fibres conducting away from the ganglion, are found. (See Fig. 4576, ramus communicans.)

Of those conducting toward the ganglion, part is of centrifugal * function, being derived from cells of the spinal cord, through either the anterior or the posterior † roots; another part are possibly fibres of afferent or centripetal (sensory) function, running from a peripheral nerve through the ramus communicans into the ganglion; at least the existence of such fibres is theoretically required. Of the second class of fibres of the ramus communicans—namely, of those conducting away from the ganglion—some are centrifugal or efferent (although not necessarily strictly motor), originating from cells of that or an adjoining ganglion, and, after having joined the cerebro-spinal nerve with which the ramus communicans of centrifugal function is connected, pass within the nerve toward the periphery, reaching the latter by way either of the anterior or of the posterior division of the nerve (see Fig. 4576, ramus communicans). Others of those fibres which conduct away from the ganglion also originate from cells of the latter or of an adjoining ganglion, but on reaching the cerebro-spinal nerve do not pass toward the periphery, but into the spinal ganglion of said nerve, terminating, according to Cajal, in free ramifications around the cells of that spinal ganglion, thus transmitting the sensory or, more generally speaking, afferent impulses from the sympathetic to the cerebro-spinal system. According to Dogiel, who distinguishes two types of cells in the spinal ganglion, the said fibres terminate around cells of the "second" type, and the latter cells again transfer to the *typical* spinal ganglion cells the impulses derived from the sympathetic system.

Grossly, a ramus communicans can usually be separated into two parts, a gray ramus and a white ramus. The white ramus contains fibres passing into it from both roots of the corresponding spinal nerve, principally from the anterior root; the gray ramus contains mostly fibres destined for the periphery, although some of them are distributed to the vessels of the spinal cord and the nerve roots.

The Peripheral Rami (see Fig. 4576, ramus periphericus).—The peripheral nerves of the sympathetic nervous system are made up of nerve fibres of two kinds, medullated and non-medullated (fibres of Remak). The non-medullated or fibres of Remak form the chief constituent of the sympathetic nerves. These nerves pass into the walls of the vessels of the viscera, or into the glands of the intestinal and urogenital system. The peripheral sympathetic nerves may be classified functionally into three kinds—motor, sensory, and secretory; and probably a group of inhibitory fibres corresponds to each of these three groups.

The motor are destined to innervate the muscles of the vessels and the viscera. The motor fibres innervate also a certain number of striated muscles, such as the heart (Huber), the upper part of the œsophagus, and the pharynx. The secretory fibres go to the glands of the intestine and urogenital system, to the sweat glands, the mucous glands, etc.

The sensory fibres terminate by free ramifications between the epithelial cells of the mucous membranes or in the depths of the walls of the viscera and the vessels, or between the formative elements of the glands (Dogiel, Schematkin, Huber). When they terminate between the two layers of the mesentery, they constitute the Pacinian corpuscles.

Kölliker thinks that all the sensory fibres of the sympathetic system belong in reality to the cerebro-spinal system. Dogiel, on the contrary, it seems to us, has shown, and is confirmed in this by Huber, that in the peripheral organs which are dependent on the sympathetic there exist special nerve cells of sensory nature, whose protoplasmic prolongations terminate between the epithelial or endothelial cells, and whose axis cylinders terminate centripetally in a sympathetic ganglion in order to make connection with the cells of origin of a motor fibre, and constitute with this last a reflex nerve arc, as in the cerebro-spinal system.

The peripheral nerves of the sympathetic nervous system present a mode of distribution which is characteristic and which distinguishes them from the cerebro-spinal nerves proper. They have a remarkable tendency to unite, to interlace one with another, and to form plexuses. The nodes of these plexuses, which are frequently of considerable size, constitute the peripheral ganglia. The nerve cells themselves are of the multipolar type, and they have innumerable protoplasmic prolongations and one axis-cylinder prolongation (van Gehuchten's researches on adult cat and dog).

Histology of the Plexuses and the Monocellular Ganglia.—The ganglia of the cœliac and hypogastric plexuses, the ophthalmic and sphenopalatine ganglia, and probably the ganglia of the heart are of a similar constitution to the ganglia of the great sympathetic chain. According to Ramon y Cajal, the cells have a fibre of Remak, or an axis-cylinder prolongation, which leaves the ganglion to join a ramus communicans or to form a peripheral branch passing to the organ which it supplies; and, in addition, there are the protoplasmatic prolongations which end near the cells of their origin within the ganglion itself.

The peripheral ganglia (visceral ganglia of Cajal), *i.e.*, the ganglia of the intestines, the bladder, the œsophagus, etc., are composed of small multipolar cells, the expansions of which, after extensive ramifications, pass into the plexuses which terminate either in non-striated muscular fibres or in glandular cells. In addition to these they

* *I.e.*, efferent function, usually motor but not necessarily so, as inhibitory fibres, too, may be of efferent function.

† That motor fibres are contained in the posterior roots has been demonstrated directly histologically by Lenhossek, who in the chick saw fibres which originated in the spinal cord enter into the posterior root, and indirectly, that is, by physiological experiment, by Morat, who proved the presence of vaso-dilator fibres in these roots.

contain, according to Cajal, fibres of passage* which are possibly the continuation of fibres from the grand sympathetic chain and collaterals which end between the nerve cells. He believes that there are no anastomoses between the visceral ganglia, the fibres of passage, or the collaterals of the visceral ganglia. Cajal describes small monocellular ganglia which are found in the interstices of the glandular tisssue or in the intestines within the villi; such are the interstitial nerve cells of the glands of Lieberkühn, the nerve cells of the pancreas, and those of the salivary glands. He calls these cells interstitial ganglia, in contrast with the ganglia of the order of Auerbach's and Meissner's plexuses, which he refers to as visceral ganglia, properly called.

Each gland, and perhaps each group of non-striated muscular fibres, no matter how small it may be, contains interstitial nerve cells, the expansions of which help to build up the plexus formed by the visceral ganglia and the fibres of the great sympathetic nerve.

Arnstein observed the neuraxon of a sympathetic neurone ending in smooth muscle tissue. Huber traced small branches of non-medullated fibres from some of the small ganglia found in the cat's auricle to their ending in heart muscle, and also the neuraxes of sympathetic neurones of the sublingual ganglion (Langley) to the epilamellar plexus surrounding alveoli of the gland of the same name.

In the pia mater of the brain Huber found two kinds of nerve fibres, medullated and non-medullated ones. The former he considers to be sensory and to end for the most part with their varicose, non-medullated, terminal branches in fibrous tissue—*i.e.*, adventitia of vessels—or in the pia. The non-medullated fibres he considers to be vaso-motor nerves, forming primary plexuses in the adventitia. Through frequent branching of the fibres of the latter an interlacing network is formed. Within this plexus is formed a second one, not so well defined, lying evidently internal to the muscular coat and giving off terminal fibrils to the muscular tissue of the vessels. In the dura cerebri Huber found sympathetic nerves forming perivascular plexuses and medullated sensory nerves, terminating in the dura. It would seem that the termination of the sensory fibres at one end must spread over a relatively large area, thus precluding a finer localization of sensory impressions.

PHYSIOLOGY.

General Facts and Functional Classification.—It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lachrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the calibre of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genito-urinary system, of the hair follicles (pilomotor nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfil its function for weeks after all the cerebro-spinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*.

In discussing the processes which are said to be under the influence of the sympathetic system, we shall subdivide the subject as follows:

I. Secretory influence:
  (*a*) Lachrymal glands.
  (*b*) Sweat glands.
  (*c*) Mammary glands.
  (*d*) Glands of the digestive apparatus.
    1. Salivary glands.
    2. Glands of the stomach and intestine.
    3. Liver.
    4. Pancreas.
  (*e*) Kidney.
  (*f*) Glycosuria.*
II. Vascular functions.
III. Cardiac functions.
IV. Respiratory functions.
V. Influence upon involuntary automatic motions.
  (*a*) Stomach and intestines.
  (*b*) Bladder.
  (*c*) Uterus, etc.
  (*d*) Pilomotor nerves.
  (*e*) Pupil.
VI. Trophic and tonic functions.
VII. Reflex action of the sympathetic.
VIII. Functional interrelation of cerebro-spinal and sympathetic systems.

I. Secretory Functions.—The sympathetic system has been proven to exert its influence on the secretion of the lachrymal glands, of the glands of the stomach and intestine (including the pancreas), of the salivary glands, of the sweat glands, and on the secretion of bile and urine. We shall mention here for convenience' sake, although not really coming under this heading, the relation of certain lesions of the sympathetic to the production of glycosuria.

Matthews (1897) has recently given the mechanism of secretion a careful experimental study, and his conclusions are of such vital interest that no one can afford to neglect them in discussing the physiology of secretion. We give these conclusions in his own wording:

"There is no single mechanism of secretion. In some glands the stored metabolic products are driven out of the cells by the action of muscle, as in amphibian skin glands and sudoriferous glands; in others they are removed by currents of lymph, which are probably the result of osmosis, as in the pancreas, stomach, salivary glands; in some cases the cells imbibe water until they burst and their contents rush into the gland lumen, as in the intestinal cells of ptychoptera larvæ; in others the inner end of the cell crumbles to pieces, as in the mammalian milk glands. Two or more of these mechanisms may coexist in one gland, and it is this which has rendered the physiology of such glands as the salivary so confusing. Whether secretory nerves exist or whether secretion is ever a function of the gland cell must be considered at present an open question."

(*a*) *Lachrymal Secretion.*—According to Demtschenko and Wolferz, excitation of the sympathetic nerve of the neck (in cats) causes lachrymal secretion. The sympathetic lachrymal secretion differs physically from the trigeminal secretion; for the former is cloudy, and the latter clear and transparent. Bechterew and Mislawski confirm this statement of the influence of the cervical sympathetic nerve upon lachrymal secretion. They find, moreover, that both the cerebral cortex (internal parts of the anterior and posterior portions of the sigmoid convolutions) and the thalamus (circumscribed spot in the depth of its internal part at the level of the anterior portion of the gray commissure) preside over lachrymal secretion by way of the fifth nerve, partly also by way of the cervical sympathetic.

G. Fischer excited the cervical sympathetic nerve with the faradic current in the heads of two decapitated men, and found as a result considerable lachrymal secretion besides the oculo-pupillary effects mentioned on page 587. Jonnesco also found the presence of secretory fibres for the lachrymal glands in the cervical sympathetic of man, his conclusions being derived from a study of epileptics in whom therapeutically the cervical sympathetic had been cut or removed.

(*b*) *Sweat Secretion.*—Although it stands unquestioned that sweat secretion is under the control of the nervous system, the manner of this influence is still a matter of debate. While it seemed to have been proven by Luch-

* Meaning fibres which only pass through the ganglion without in any way becoming connected with the cells of the latter.

* Taken under this heading for convenience' sake.

singer that this influence was a direct one, and not one acting indirectly, through vascular effect, his results have again been made doubtful by the recent researches of Matthews, who concludes that the sweat glands, like the salivary glands, receive a double nerve supply and probably possess a double mechanism of secretion, *i.e.*, a muscular and an osmotic, as explained on page 582.

Vulpian distinguishes for the salivary glands secretion-exciting nerve fibres (fibres excito-sudorales), and, antagonistic to these, sweat-moderating fibres. The subject has not been followed up, however, and the physiological facts, which have thus far come to the writer's knowledge, concern only sweat-exciting fibres.

The pathway pursued by the sweat-secretory fibres in their course from the spinal cord to the sweat glands is not fully known in its whole extent. They leave the spinal cord by the anterior roots. Whether the posterior roots conduct some of these fibres has never been debated. The statements as to their further course are very diverse. All authors admit, it seems, that part of the fibres pass through the great gangliated cords before joining the peripheral nerves, and some writers (Nawrocki and Luchsinger, and Langley) go so far as to say that all sweat fibres destined for the limbs are derived *indirectly*, *i.e.*, through intermediation of the sympathetic nerve, from the spinal cord, a view opposed by Vulpian and later modified again even by Luchsinger as far as the hind paws of the cat were concerned.

Regarding the sweat fibres for the fore paws, views have been equally divided; Vulpian claiming on the one hand that part of the sweat fibres go directly from the spinal cord to the brachial plexus; Luchsinger, and lately Langley, contending on the other hand that all sweat fibres for the forepaw enter the thoracic sympathetic and pass through the stellate ganglion before joining the nerves of the brachial plexus.

In two cats in which Dr. Collins and myself had extirpated a stellate ganglion, sweat secretion could be produced in the fore paw of the operated side three and four and one-half months after the operation respectively, in one case by hypodermic injection of pilocarpine, in the other by instillation of the latter into the eyes. In one of these two cats, when etherization was begun for the purpose of performing another operation, the struggles of the animal against being etherized produced considerable sweating of all paws except the forepaw of the side on which the stellate ganglion had been removed; this forepaw remained perfectly dry. These observations tend to throw some doubt on the contention of Langley and Luchsinger, mentioned at the end of the above paragraph, although their interpretation is by no means simple.*

For the sweat glands of the head, even Luchsinger admits both a sympathetic (fibres of the cervical sympathetic nerve) and a direct non-sympathetic nerve supply, the latter being furnished either by the spinal cord or by the oblongata. Luchsinger emphasizes the view, however, that the cervical sympathetic nerve is the principal sweat nerve for the head. (In pigs and cattle certain glands of the muzzle of cattle are the homologues of sweat glands.)

In man the presence in the cervical sympathetic nerve of sweat secretory fibres for the head was found by Jonnesco, who experimented on fifteen epileptics in whom the cervical sympathetic nerve was cut or resected for sake of treatment.

(*c*) *Lacteal Secretion.*—Of the special influence of the nerves upon the mammary glands and upon the secretion of milk, we know only that while erection of the nipple is impossible when the spinal nerves which supply the breasts are divided, the secretion continues and is not arrested even when the sympathetic as well as the spinal nerves are severed (Foster).

(*d*) *Secretion of the Glands of the Digestive Apparatus.*—1. *Salivary Secretion.*† Secretion of the parotid gland occurs not only by influence of cerebral nerve fibres, but also by that of the sympathetic nerve of the neck (von Wittich and Nawrocki). Secretory fibres for the salivary glands were also found by Jonnesco in the cervical sympathetic of man (experiments on fifteen epileptics who had the cervical sympathetic cut or removed). In their course toward the gland the secretory fibres of the cervical sympathetic become connected with the facial nerve (von Wittich).

The presence of real secretion-promoting or secretion-inhibiting fibres for the parotid gland in the cervical sympathetic nerve is denied by Jaenicke and doubted by Eckhard, the former explaining the "sympathetic" secretion of saliva purely by vaso-motor function.

Heidenhain finds (in rabbits and dogs) that parotid saliva secreted by excitation of the cervical sympathetic nerve differs from that obtained from excitation of the cerebral secretory fibres (nervus Jacobsoni) by its high percentage of organic, especially of albuminous, substances. To explain this effect—which, he says, takes place quite independently of the vaso-motor function of the sympathetic nerve—he assumes that the latter acts more through trophic than through secretory function upon the parotid.

Langley, who repeated Heidenhain's experiments, found that under the influence of excitation of the "trophic" fibres the number of granules seen in the protoplasm of the cells of the parotid gland increased considerably, while it diminished under the influence of the secretory fibres. He found, however, that in the *cat* the trophic fibres are not contained in the cervical sympathetic, but, on the contrary, in what is considered the cerebro-spinal secretory nerve, viz., in the chorda tympani.

In the light of Matthews' investigations Heidenhain's theories and the generally accepted trophic nerve mechanism of secretion are very questionable. Matthews concludes that the sympathetic nerve induces salivary secretion by acting on contractile tissue in the glands and thus causing a compression of ducts and alveoli; that, on the other hand, the chorda tympani or other dilator salivary secretory nerve probably causes secretion by its dilator action on the blood-vessels, thus increasing osmosis.

2. *The Glands of the Stomach and Intestine.* The secretion of gastric juice in frogs continues for days (until death) after all connections of the stomach, except the mesentery deprived of its nerves, have been severed, showing that the centres presiding over the secretion of gastric juice are situated in the intragastric plexuses (Contejean). In these animals the pneumogastric and sympathetic nerves have a regulatory influence upon the secretion of the stomach glands.

Regarding the intestine, Moreau observed that after separation of a piece of intestine from the rest of the gut by two ligatures and severance of all nerves of the mesentery leading to it, this isolated piece of gut filled itself with an apparently abnormal secretion fluid.

The influence of special nerves upon the secretion of intestinal juice was studied by Dr. J. Collins and the writer with this result: Disturbance of digestion followed the removal of the stellate ganglion and of the lower thoracic portion of the sympathetic cord, and also the removal of a semilunar ganglion in the cat. The digestive disturbances following extirpation of the stellate ganglion were, however, more marked and more persistent than those noted after removal of the lower thoracic sympathetic. They consisted of diarrhœa and of putrefaction of the fæces. The fæcal matter was semiconsistent, of yellow or dark grayish-brown color, and of exceedingly foul odor.

The putrefactive symptoms made their appearance sometimes as late as two and three months after the operations, and it was noted that the digestive disturbances had a tendency to increase, and, in two cases, persisted until the death of the animals, three and four and one-half months, respectively, after the operation. This

* For a detailed discussion of the question the reader is referred to the monograph by Dr. Collins and the writer. (See Bibliography.)

† Claude Bernard's observations on the submaxillary gland and ganglion are referred to farther on, under the heading "Tonic Influence."

tendency of the symptoms is most plausibly explained by degeneration progressing toward the periphery and affecting finally the intrastomachal and intra-intestinal plexuses.

Vomiting was observed occasionally after removal of the stellate ganglion or of the lower part of the thoracic sympathetic or of the semilunar ganglion, but this symptom was very inconstant and transitory.

3. *Secretion of the Bile.* Munk observed that excitation of the splanchnic nerve in rabbits was followed first by an acceleration, then by a retardation of the flow of bile. He attributes this effect chiefly to vaso-motor influences and to stimulation of the muscles of the gall ducts. The latter effect was also noted by Doyon (quoted from Howell), who states that the corresponding nerve fibres reach the liver through the semilunar plexus.

Afanassiew noted that section of the nerves of the liver gave rise to polycholia: (*a*) increased secretion of bile; (*b*) dilatation of all the blood-vessels of the liver to a marked degree, and afterward dilatation of the lymphatic pathways; (*c*) excess of urobilin, its presence being caused partly by the polycholia and partly by compression of the fine gall ducts by the dilated blood and lymph vessels, the consequence being retention of bile; (*d*) absence of glycogen in the liver; (*e*) swelling of the liver cells, which take on an appearance similar to that observed after fibrin feeding.

Howell concludes that, as far as our knowledge goes, the physiological evidence is against the existence of true secretory nerves controlling the formation of bile. On the other hand, he says, there are some experiments (Morat and Dufour), though not absolutely conclusive, which indicate that glycogen formation within the liver cells is influenced by a special set of glyco-secretory fibres.

4. *Influence upon the Pancreatic Secretion.** According to the investigations of Pawlow and his students, stimulation of the vagus nerve or the sympathetic causes, after a considerable period of latency, a marked flow of pancreatic secretion Howell says that, in harmony with the theory of trophic and secretory fibres, the experiment seems to indicate that trophic fibres are more abundant in the sympathetic, and, similarly, the secretory fibres proper in the pneumogastric.

(*e*) *Renal Secretion.*—Howell concludes that the majority of purely physiological experiments upon direct stimulation of the nerves going to the kidney are adverse to the theory of secretory fibres, the marked effects obtained in these experiments being entirely explicable by the changes produced in the blood supply of the organ. Hermann comes to similar conclusions.

The vascular nerve fibres of the kidney are supplied by the renal plexus, and are preponderatingly but not exclusively derived from the splanchnic nerves (Hermann). According to Bradford, the innervation of the vessels of the kidney is furnished by the anterior roots of the dorsal nerves from the fourth downward and of the lumbar nerves down to the third and fourth; most abundantly, however, by the eleventh, twelfth, and thirteenth dorsal. The existence of fibres passing within the splanchnic to the kidney, fibres which exert a tonic influence, cannot be proven (Hermann). According to Langley and Dickinson, the splanchnic vascular fibres of the kidney are interrupted by cells of the renal plexus.

Peyrani has found that section of the cervical sympathetic causes a lessening of the quantity of urea and urine to a minimum, while excitation of the peripheral (head) stump of this nerve causes increase both of urea and of urine. Kuelz could not confirm these results, and denies that the cervical sympathetic has any influence upon the above-mentioned secretions.

(*f*) *Glycosuria Produced by Influence of the Sympathetic.*—The subject of glycosuria is ranged in here for convenience' sake, although not properly belonging here.

Since Claude Bernard showed that irritation of the floor of the fourth ventricle, the so-called hepatic vaso-motor centre or area, causes glycosuria, physiological and pathological evidence has been accumulated to show that the production of grape sugar stands in causal relationship to the function of the sympathetic nervous system. Schiff demonstrated that section of the vaso-motor pathways in the spinal cord at any level down as far as the exit of the nerves for the liver, caused glycosuria. Pavey noted that destruction of the superior cervical ganglion caused glycosuria, and Eckhard observed that a similar condition resulted when the inferior cervical and first thoracic were destroyed. Trambusti showed experimentally that after extirpation of the cœliac plexus there was deposition of glycogen in the kidneys. Dr. J. Collins and the writer found much sugar in the urine in one cat four weeks after removal of the lower part of the thoracic sympathetic nerve on one side, in another cat four months after the same operation. Nearly every physiologist who has experimented on the abdominal sympathetic, and has afterward carefully observed the constitution of the urine, has found that lesion of this part of the sympathetic is accompanied usually by glycosuria (Klebs, Munk, Hensen); but in most if not all of these experiments only the immediate effects of lesions in the domain of the sympathetic were studied, while in the observations of Dr. Collins and the writer the remote effects of such lesions were the subject of inquiry.

The hypotheses that have been advanced to explain the occurrence of glycosuria with these experimental lesions of the sympathetic nervous system are numerous. The majority of writers seem to be of the opinion that the occurrence of grape sugar with such lesion is immediately conditioned by change in the tonus of the blood-vessels of the liver and in the quantity of blood passing through the liver.

From the large amount of sugar found four months after the lesion of the thoracic sympathetic, it is fair to conclude that the glycosuria caused by such lesions is not temporary but permanent, and seems, if we are allowed to judge anything from the observations of Dr. Collins and myself, limited to two cases only, to have a tendency to increase rather than to diminish.

We find, then, that nearly all secretory glands are under the influence of the sympathetic system. The facts indicate, as Claude Bernard showed for the submaxillary ganglion and gland, that there are independence and dependence of action of the peripheral (that is, sympathetic) secretory nerve apparatus from the central nervous system. The fibres of the latter (cerebro-spinal fibres, motor fibres of the first order—Kölliker; preganglionic fibres—Langley) exert a controlling influence upon the secretions, which influence is either stimulating or inhibitory, purely secretory or partly vascular, or solely vascular, as in the case of the kidney, for instance, in which organ the existence of purely secretory fibres could not be proven. For some glands (salivary, pancreas) the existence of true trophic nerves is possible, although rendered questionable by Matthews' conclusions, and it would seem that most of the trophic fibres are derived from the sympathetic cord.

II. Vascular Functions.—The investigations of Claude Bernard, Dastre and Morat, Ostroumoff, Gruetzner, Heidenhain, and others have demonstrated the existence of two kinds of vascular nerve fibres (fibres calorifiques of Claude Bernard). The excitation of one kind causes vaso-constriction—"vaso-motor or vaso-constrictor fibres"; while excitation of the other kind produces vaso-dilatation—"vaso-dilator or vaso-inhibitory fibres." The vaso-constrictor fibres usually predominate in number or strength, and are therefore more easily demonstrated than the vaso-dilators.

As to *sensory* vascular nerve supply, Spallita and Consiglio find that the entire vascular surface is provided with special sensibility, capable of producing notable modifications in the general distribution of the blood. It is the opinion of these investigators that the function of the vaso-sensitive nerves is to prevent a superabundance of blood in the peripheral parts of the circulatory

* See results of Matthews' experiments, p. 582.

system, an action analogous to that which Cyon admitted for the sensory nerves of the heart and of the liver.

The motor vascular fibres leave the spinal cord for the most part with the anterior roots, but a part of the vaso-dilator (vaso-inhibitory) fibres seem to be contained in the posterior roots (Stricker, Gaertner, Morat). In their further course the vascular fibres either join the great gangliated cord by means of communicant rami, which is the case for most if not all vascular fibres of the limbs (Claude Bernard, Ostroumoff, Heidenhain and Gruetzner, Langley), or they pass from the spinal nerve directly to one of the great prevertebral plexuses. We find thus, for instance, that part of the vascular fibres supplying the pelvic viscera are derived from the lumbar plexus and join the periphery by intermediation of the great gangliated cord, while the other part, arising from the sacral nerves, pass directly to the hypogastric plexus without connection with the gangliated cord (Langley).

Many of the vascular fibres enter the gangliated cord and become interrupted by cells of the ganglia of the latter. This is probably the case with most of the vaso-motor and vaso-inhibitory fibres for the limbs. Others again, those which are contained in the posterior roots, are said to be interrupted by cells of the spinal ganglia (Morat). Still others take an uninterrupted course through the sympathetic cords, using the latter only as a kind of commissure. This has been demonstrated to be so for the vascular fibres of the splanchnic nerve, which pass without interruption from the spinal cord either to the semilunar or to the superior mesenteric ganglion (Langley and Dickinson).

The presence of both vaso-constrictor and vaso-dilator fibres has been proven in almost every division of the sympathetic system.

Recently the section or resection of the cervical sympathetic unilaterally or bilaterally has given opportunity of studying the vascular functions of this part of the gangliated cord in man. Jonnesco, making his studies on fifteen epileptics thus operated, concludes that the cervical sympathetic contains vaso-constrictor fibres for the head, face, and heart, made evident by excitation with strong electric currents; that it contains, furthermore, vaso-dilator fibres for the inner parts of the cheeks and lips, for the gums, inner and lateral part of the tongue, and for the brain, brought out by the application of feeble currents.

In rabbits, Lafforgue had observed as the direct result of stimulation of the cervical sympathetic nerve (peripheral stump) a spasmodic ischæmia of the whole cerebrum, cerebellum, and oblongata.

A common central organ for the vaso-motor nerves is situated in the medulla oblongata, by stimulating which (the spinal cord and sympathetic being uninjured) contraction of all the small arteries, increase of the blood pressure in the arterial trunks, and turgescence of the heart (Ludwig and Thiry, quoted from Hermann), will be produced. It extends in rabbits from about 3 mm. above the calamus scriptorius to the upper portion of the fourth ventricle. It is bilateral, situated at some distance from the median line.

Reinhold, in several cases of vascular disturbances which by exclusion were interpreted as being of central origin, found multiple hemorrhages at the floor of the fourth ventricle.

The outflow from the spinal cord, of the vaso-motor fibres for the lungs (in the dog) takes place between the first and fifth dorsal nerves, with a maximum at the level of the third dorsal. Some of these fibres leave the thoracic sympathetic chain at the level of the stellate ganglion and pass through the ansa Vieussenii to the inferior cervical ganglion (Bradford, Dean, and François Frank).

III. Cardiac Functions.—The striking autonomy of the peripheral nerve apparatus of the heart is shown by the fact that the latter, when removed from the body or deprived of all the nerves passing to it, still continues to beat for some time, in cold-blooded animals even for days. Recently Engelmann has called attention to a still more marked autonomy of the heart's action, pointing out that in the fœtus pulsations of the heart begin at a period when the latter is still absolutely devoid of nerve-cells (and consequently also of nerve-fibres). In the human embryo the first beginnings of cardiac ganglia are not found before the end of the fourth or commencement of the fifth week (His), while Pflüger saw regular pulsations of the heart in a human embryo of hardly three weeks, which denotes the possibility of purely myogenic heart action entirely independent of any nervous influence. Yet its action is under the control of certain nerves, part of which have an accelerating and at the same time augmenting (intensifying) influence—augmentor nerves; while the others have an inhibitory effect by lessening the number of beats and the force of the contractions—inhibitory nerves of the heart. Most of the inhibitory nerves are contained in the pneumogastric nerve, which is the cardiac inhibitory nerve *par excellence*.

In the dog the augmentor fibres are said to leave the spinal cord by the anterior roots of the second and third and to some extent the first and fourth, possibly the fifth, thoracic nerves. They travel by the several rami communicantes to the stellate ganglion, and pass thence to the cardiac plexuses and to the heart by nerves from the ganglion itself or from the ansa Vieussenii, or from the so-called lower cervical ganglion. In the cat, and probably in mammals generally, the path of the augmentor impulses is very similar. They leave the spinal cord by the upper thoracic nerves and pass to the heart through the lower cervical and upper thoracic sympathetic ganglia (Langley, Foster).

Part of the augmentor fibres, however, are derived from the pneumogastric nerve (Hermann). Schiff, who goes so far as to claim that the pneumogastric alone contains augmentor fibres, says that when this nerve is completely degenerated no acceleration of the heart action can be obtained through any nerve. He concludes that the influence which the sympathetic ganglia have upon the acceleration of the heart's action is due to the action of the pneumogastric nerve connected with them.

IV. Respiratory Functions.—Graham finds that the splanchnic nerve exerts a reflex, inhibitory influence upon respiration. If the splanchnic nerve of the one (left) side is severed and the central stump excited by the faradic current, the respiration arrests itself in the state of expiration—diaphragm perfectly relaxed, abdominal muscles contracted. The tests succeed also when both pneumogastric nerves are severed at the neck.

Section of the oblongata above the region of the respiratory centre does not influence the result, which remains also unchanged when the spinal cord is severed between the eleventh and twelfth dorsal vertebræ, while the excitation of the splanchnic nerve loses its effect if the section is made between the fourth and fifth dorsal vertebræ. This shows that the fibres in question enter from the splanchnic nerve into the spinal cord above the eleventh or twelfth dorsal, and below the fourth or fifth dorsal vertebræ, and then ascend to the oblongata to influence the respiratory centre.

Guillebeau and Luchsinger confirm Graham's observation of the influence of faradic excitation of the splanchnic nerve upon respiration if the spinal cord is intact; but if the oblongata is severed from the cord, the effect of the faradization of the splanchnic nerve is contraction, not only of the abdominal muscles, but of the diaphragm. They contend that the spinal cord contains the primary centres for abdominal *pressure* (*Bauchpresse*), because after isolation from the oblongata the mechanics of the abdominal pressure can be brought into action reflexly by excitation of sensory nerves.

It may be of some interest briefly to mention here the remote effects of lesions of the sympathetic on respiration and on the respiratory tract in general, as observed by Dr. J. Collins and the writer after removal of the lower part of one thoracic sympathetic nerve in some cats and of one stellate ganglion in others. These effects, as a rule, made their appearance as late as weeks after the operation, and, in the case of lesion of the thoracic sympathetic, even four months after the injury inflicted. They consisted in either case in the occurrence of attacks of sneezing and of paroxysms of coughing and hiccough. Removal of the stellate ganglion caused, in addition, first a mucous, then a purulent secretion from the nasal mucous membrane, and in one case it produced a chronic purulent bronchial secretion with lobular infiltration of the lungs.

The respiratory symptoms were more grave in the case of removal of the stellate ganglion than in the case of resection of the thoracic sympathetic in its lower portion. To account for this we must not forget that in the cat the vagus nerve sends a powerful communicating branch to the stellate ganglion. This may also explain the presence of the catarrhal condition in case of removal of the stellate ganglion and its absence in the case of resection of the lower portion of the thoracic sympathetic. The cough and hiccough, however, could not be due to involvement of the pneumogastric alone, since they were observed also after resection of the lower part of the thoracic sympathetic, an operation which involved chiefly the splanchnic nerve. For the innervation of the pulmonary vessels, see page 585, end of section on vascular functions.

V. Involuntary and Automatic Movements.—Under this heading I class the movements caused by non-striated muscles. The heart muscle has a structure which forms a transition between the striated and non-striated muscles. Owing to the intimate connection which exists between the heart and the blood-vessels, it was found most convenient to discuss the sympathetic influence upon this organ directly after discussing the vascular functions.

It now remains to discuss the influence of the sympathetic system upon the movements of the stomach and intestines, the bladder, the uterus, the pupil, and on the erectors of the hair follicles (pilomotor nerves, Langley).

(*a*) *The Movements of the Stomach and Intestines.*—In this paragraph we may at the same time discuss the vascular influence upon the stomach and intestines. The nerves presiding over the secretions of these parts have been spoken of in a preceding chapter.

The movements of the stomach and smaller intestine are under the control chiefly of the pneumogastric and the splanchnic nerves, which nerves are to a large extent functionally antagonistic to each other (Pflüger, Mayer and Basch, van Braam-Houckgeest). The pneumogastric is chiefly a vaso-dilator nerve and excites the movements of the intestine and the stomach; the splanchnic inhibits the movements, and it is at the same time vaso-constrictor. Morat has demonstrated, however, that this antagonism is not absolute, he being able to demonstrate the inhibitory activity of the pneumogastric and, on the other hand, the excito-motor (augmenting) activity of the splanchnics.

One splanchnic nerve can functionally replace the other (van Braam Houckgeest). Both the vaso-constrictor and the motor inhibitory action of the splanchnics are under the tonic innervation of the nerve centres (spinal) with which they are connected (van Braam-Houckgeest).

According to Contejean, the pneumogastric nerve in the frog innervates the longitudinal system of muscular fibres of the stomach, and contains also inhibitory fibres which may counteract reflex action of the stomach; the sympathetic, on the other hand, presides chiefly over the circular system of muscles.

Ehrmann, on the other hand (quotation from Hermann), finds that the pneumogastric excites the circular muscular fibres of the stomach and intestine and inhibits the longitudinal fibres, while the splanchnic excites the longitudinal fibres and inhibits the circular fibres. This conclusion is contradicted by Langley.

According to Langley, the splanchnic fibres are derived directly from the spinal cord; that is, they undergo no cell interruption in the ganglia of the sympathetic cords. But they have their termination in the semilunar ganglia, and from the cells of the latter new fibres arise which establish the connection with the muscles and blood-vessels of the stomach and upper intestine.

The lower segments of the intestine (colon and rectum) receive likewise a double nerve supply, namely from the lumbar (second to sixth in the cat), and from the sacral (second to fourth) nerve roots (Langley and Anderson). The fibres derived from the lumbar roots (visceral lumbar nerves) join the sympathetic and leave it for the most part with the cœliac or hypogastric nerves. The fibres derived from the sacral roots (visceral sacral nerves) pass into the nervi erigentes.

The two nerve plexuses differ not only in origin, but also in function (Langley and Anderson). In the first place the visceral lumbar nerves contain vaso-constrictor fibres for the descending colon, for the rectum, and for the mucous membrane of the internal sphincter. These nerves further contain inhibitory fibres for the muscles of the colon and rectum and for the mucous membrane of the internal sphincter. Finally, the visceral lumbar nerves have a relationship to the skin surrounding the anus; they supply motor fibres for the non-striated muscles and for the constrictors of the blood-vessels of this region.

The visceral *sacral* nerves are to a great extent antagonists of the visceral *lumbar* nerves. Excitation of them produces hyperæmia of the intestinal mucous membrane and strong movements of the longitudinal and circular muscles of the colon and rectum. The non-striated muscles of the skin of the anus are inhibited by these fibres.

In regard to the movements of the rectum Fellner had come to the following conclusions, which are, as we have seen, contradicted in part by Langley and Anderson: (1) The nervi erigentes cause contraction of the longitudinal fibres and relaxation of the circular fibres of the muscles, shortening and thickening of the rectum, increase of volume, and diminution of pressure; (2) the hypogastric nerves have the opposite effect: relaxation of the longitudinal, contraction of the circular muscular fibres, lengthening and narrowing of the rectum, lessening of volume, and increase of pressure.

(*b*) *The Movements of the Bladder.*—It is proven by the investigations of Budge, Sokownin, Gianuzzi, Nussbaum, Nawrocki and Skabitschewski, Langley and Anderson, and Sherrington that the bladder receives a double supply of motor nerves, viz.: (1) From roots of lumbar nerves (lumbar supply); and (2) from sacral nerves (sacral supply).

The fibres derived from the *lumbar nerves* leave the spinal cord by the anterior roots of the (third) fourth and fifth (in the monkey from the second, third, and fourth) lumbar nerves, and join the abdominal sympathetic nerve by the rami communicantes. From the abdominal sympathetic part of the fibres pass directly to the hypogastric and vesical plexuses (Nussbaum); the greater part, however, reach the inferior mesenteric ganglion by way of the mesenteric (superior, median, inferior) nerves, and pass then into the hypogastric nerves, which latter connect the inferior mesenteric ganglion with the hypogastric plexus.

The fibres derived from the *sacral nerves* leave the spinal cord with the anterior roots of the second, third (sometimes also the fourth, and very seldom the fifth) sacral, and pass from these nerves *directly to the hypogastric plexus*, without mediation of the main trunk of the sympathetic.

According to Langley, part of the motor fibres of the bladder are interrupted by cells of the inferior mesenteric ganglion, others probably by the cells of the hypogastric or vesical plexuses.

As the descent of the fibres to the bladder occurs in two different pathways, so their origin in the cord is probably twofold; that is, we must assume for many mammals the presence of two separate spinal centres of the bladder, one being situated in the lumbar, the other in the sacral portion of the cord. The position of these centres, although not exactly known, is indicated more or less by the level of the roots through which the motor fibres for the bladder leave the cord. Gianuzzi claims that in the dog they are situated at the level of the third and fifth lumbar vertebræ respectively. Sarbo reported a case of a man in whom there had been incontinence of fæces and of urine, and in whom the autopsy revealed a gliosis that had effaced the structure of the spinal cord almost entirely at the levels of the third and fourth sacral segments.

Erection and Ejaculation. The vaso-dilator fibres, stimulation of which causes erection, are contained in the nervi erigentes (Eckhard, quoted from Hermann) which are formed by filaments passing from the sacral nerves (chiefly the second and third) to the hypogastric plexus; but some of these vaso-dilator fibres come from the lumbar sympathetic (dog), passing from there to the hypogastric plexus (François Franck).

Concerning the pathways of the nerves presiding over ejaculation, nothing definite seems to be known. At least nothing is said about them in the well-known physiological text-books.

The centres of erection and ejaculation (dog) are situated in the lumbar portion of the spinal cord (Goltz).

As has been mentioned in another paragraph, the bladder can act independently of the spinal centres, at least in the higher mammalians (cat, monkey). After all the motor fibres leading to the bladder have been severed from the spinal cord, this organ still continues its functions for weeks (Zeissl). Its rhythmic action is the result of the nerve apparatus (hypogastric and vesical plexuses) placed within or on its wall (Zeissl, Sherrington).

(*c*) *The Movements of the Uterus.*—According to Langley, all motor fibres to this organ are supplied exclusively from lumbar nerves, and their further course is within the main trunk of the sympathetic, from which they pass through the inferior mesenteric ganglion to the pelvic plexuses. Some authors, however (Frankenhauser, Kehrer, and others), claim a sacral supply in addition to the lumbar, stating that part of the motor fibres of the uterus pass directly from sacral (third, fourth) nerves to the pelvic plexuses. According to Basch and Hoffmann (quotation from Hermann), the lumbar nerves act as motor nerves only of the longitudinal fibres, the sacral only of the circular fibres of the uterus. These statements are contradicted by Langley.

A great part of the motor fibres to the uterus are interrupted by cells of the inferior mesenteric ganglion (Langley).

For parturition, the centre situated in the lumbar portion of the spinal cord is sufficient, as this act has been observed in bitches with isolated lumbar portion of the spinal cord (Goltz and others). As to whether parturition can take place if the connection with this spinal centre is severed, we can find no data.

Chapman and Foote conclude that the ovarian plexus is the controlling nerve supply to the ovary, tube, and uterus, and the path along which are conveyed the most important stimuli passing to these organs. For further details of their work, see the paragraph on the "Nerves of the Uterus" in the anatomy of the sympathetic, page 579.

(*d*) *The Erector Muscles of the Hair Follicles and the Pilomotor Nerves.*—The name of pilomotor nerves is given by Langley and Sherrington to those nerve fibres which innervate the erector muscles of the hairs. According to these authors, the pilomotor fibres pass through the anterior roots into the sympathetic nerve from which they take their course to the periphery. Experiments with nicotine prove that the fibres become interrupted* by cells of the sympathetic ganglia of the two gangliated cords. The pathway that the impulse takes from the spinal cord to the periphery consists thus of two sets of neurones, one of which originates from cells of the spinal cord, the other from cells of the ganglia of the main trunk of the sympathetic.

The outflow of the pilomotor nerves from the spinal cord occurs through the rami communicantes of the fourth dorsal (seldom the third) down to the third or fourth lumbar nerves. (In cats and monkeys it is somewhat otherwise.)

Excitation of the individual ganglia of the sympathetic nerve causes erection of hairs in definite circumscribed regions. Usually, but not always, the sympathetic (peripheral) fibres arise from cells of the nearest sympathetic ganglia, sometimes from the second nearest.

The pilomotor fibres and the sensory fibres can be traced running together up to their entrance into the skin. There is no difficulty in showing that the greater part of the area supplied with pilomotor nerves by a given gray ramus is also supplied by sensory fibres of the corresponding spinal nerve (Langley).

Langley and Sherrington allot to the various communicant rami definite circumscribed although partly overlapping areas of distribution of pilomotor fibres.

The results of some of the experiments conducted by Dr. J. Collins and the writer lead us to the conclusion, however, that although the pilomotor nerves probably have, on the whole, the segmental distribution which Langley and Sherrington attribute to them, there must be a collateral supply or a direct cerebro-spinal supply, which in the case of removal of three or four successive ganglia can in the course of time entirely replace the functional loss thus created.

(*e*) *Influence upon the Pupil, Eyeball, and Eyelids.*—In 1727 Pourfour du Petit first demonstrated that section of the cervical sympathetic nerve is followed by contraction of the pupil and sinking in of the eyeball of the corresponding side. The contraction of the pupil was interpreted as being due to paralysis of the dilator pupillæ muscle. The sinking in of the eyeball was explained partly by vaso-motor effect, partly by the paralysis of Müller's muscle (Heese).

G. Fischer (quotation from Moebius) excited the cervical sympathetic nerve in the heads of two decapitated men. Faradic excitation produced opening of the palpebral fissure, dilatation of the pupil, protrusion of the cornea, and considerable lachrymal secretion These effects on the pupil, palpebral fissure, and eyeball in man were confirmed also by Jonnesco in epileptics in whom for therapeutic purposes the cervical sympathetic was resected or cut.

Budge and others showed that the pupil-dilating fibres of the cervical sympathetic are derived from the anterior roots of certain spinal nerves, which, joining the sympathetic nerve of the thorax by means of rami communicantes, pass through the ansa Vieussenii to the stellate ganglion, from whence they take their course within the cervical sympathetic to the pupil.

Comparing the results of the investigators (Budge, Salkowski, Nawrocki, Sherrington, Langley, Müller) in this field, we find that the outflow of the pupil-dilating fibres from the spinal cord occurs with the greatest constancy in the anterior roots of the first dorsal and almost as constantly of the second dorsal, to less extent and less constantly of the eighth cervical and third dorsal, and least constantly, it would seem, of the seventh cervical and fourth dorsal nerves. This distribution varies not only with the species of the animal, but also individually in the same species.

Budge placed the origin of the pupil dilating fibres of the cervical sympathetic in the so called cilio-spinal centre, which he found to occupy the region between the exits of the sixth cervical and third dorsal nerves in the

* Langley believes that there are justifiable grounds for the conclusion that by stimulating the nerve fibres running to and from any peripheral ganglion before and after applying dilute nicotine to it, the class of nerve fibres which end around nerve cells of the ganglion can be distinguished from those which run through the ganglion without being connected with its cells. Nicotine seems to paralyze the conductive action either of the nerve cells of the ganglion or of the nerve endings in the ganglion, that is, it seems to prevent the transmission of a stimulation from one neurone to another while it does not affect the conductivity of the nerve fibres. Therefore, if the ganglion is smeared with nicotine, direct stimulation of the nerve fibres passing out *from* the ganglion to the periphery retains in every case its full effect; but if, after the application of the nicotine, stimulation is applied central of the ganglion, *i.e.*, to the nerve fibres passing *into* the latter (instead of *from* it) this stimulation will remain effective if the said fibres pass uninterruptedly through the ganglion, while it will have *no* effect if the stimulated fibres terminate around cells of the ganglion.

spinal cord. Dastre and Morat confirmed Budge's conclusions. Salkowski and Knoll denied the existence of a cilio-spinal centre, and placed the origin of the pupil-dilating fibres higher, Salkowski in the oblongata, Knoll in the anterior corpora bigemina.

On the other hand, clinical experience tended to confirm the existence of a cilio-spinal centre, since oculo-pupillary symptoms were found to accompany transverse lesions of the spinal cord in the lower regions of the cervical and the upper regions of the dorsal portion of the cord (Kraus). This evidence was not conclusive, however, since in a case of transverse lesion of the spinal cord the fibres would also be severed in their course through the white substance, even if they originated from the oblongata or corpora quadrigemina. We might say that although the evidence is preponderatingly in favor of the existence of a cilio-spinal centre, yet the question has not been definitely settled.

Coleman Balogh and François Franck showed, however, that not all pupil dilating fibres contained in the first branch of the trigeminal nerve are derived from the cervical sympathetic, but that part of them reach the Gasserian ganglion by way of the roots of the trigeminal nerve.

The observations of Dr. J. Collins and the writer corroborate the contention that not all pupil-dilating fibres are contained within the cervical sympathetic nerve, since the narrowing of the pupil following removal of the cervical sympathetic (*i.e.*, of the stellate ganglion) in cats disappeared almost entirely in the course of months, and since, furthermore, in one case in which *one* stellate ganglion was removed first and the other one three months afterward, both pupils were still found to dilate in darkness.

Concerning the further course of the pupil-dilating fibres of the cervical sympathetic, only so much is known that they all finally join the Gasserian ganglion and leave the latter with the first branch of the trigeminal nerve (Coleman Balogh, quoted by Jegorow and Dogiel). They then pass through the long ciliary nerves to the pupil without forming connections with the ciliary ganglion (Jegorow and Dogiel, Nawrocki and Przybylski).

The question whether the cervical sympathetic contains also pupil-contracting fibres has, to our knowledge, been considered only by one investigator, viz., by Dogiel, who answered it affirmatively. The experiments of Dr. J. Collins and the writer tend to confirm his view, although not in an altogether unobjectionable manner. Dogiel's researches are quoted in detail in our report.

In addition to contraction of the pupil, section of the cervical sympathetic nerve causes a sinking in of the eyeball into the orbit, slight ptosis of the upper lid, and paralysis of the nictitating membrane. Heese finds that excitation of the sympathetic nerve causes protrusion of the eyeball in cats and dogs, while in rabbits it produces very marked sinking in of the eyeball. This discrepancy he explains by the fact that the sympathetic nerve displays its effect upon the eyeball in two ways: first, by the contraction of Müller's muscle; second, by vaso-motor influence. The former causes protrusion, the latter a sinking in of the eyeball. In cats the effect upon Müller's muscle predominates, therefore the protrusion; in rabbits the reverse is true.

According to Langley, the nerve fibres causing retraction of the nictitating membrane (third lid) and opening of the eyelid have in the cat a more extended origin than the dilator fibres for the pupil. They arise from the first four thoracic nerves, and sometimes from the fifth also. In nearly every case the second thoracic is most effective, the first more than the third; the fourth has slight effect, the fifth at best causes but a trifling movement.

That the cervical sympathetic has an influence upon the shape of the cornea is claimed by Claude Bernard, Brown-Séquard, and Hermann, who find that section of the cervical sympathetic causes flattening of the cornea. Their statements have been contradicted by Heese. Heese declares that the conclusions of Morat and Doyon, who contend that the sympathetic nerve influences the shape of the lens by displaying an effect antagonistic to that of the third nerve upon accommodation, are likewise erroneous. Jaboulay found amelioration of vision in two patients after severing of the cervical sympathetic nerve between the superior and middle cervical ganglia. He attributed this amelioration, however, not to any effect on accommodation, which latter he found quite unaltered, but to the narrowing of the pupil, which influenced myopia and astigmatism favorably in the manner of a stenopaic slit.

The trophic disturbances observed in the eye after removal of the stellate ganglion will be discussed in the next section.

The hypotension of the eyeball following removal of the superior cervical ganglion disappears entirely in the course of time, at least in non-glaucomatous cases (Jonnesco, Lagrange, H. Pachon).

VI. Trophic and Tonic Functions.—(*a*) *Trophic Functions.* Regarding the supposed trophic action of the sympathetic on the salivary glands, liver, and pancreas, the reader is referred to the paragraphs of this article which treat of these organs (pages 583 and 584).

Of other trophic effects, I mention, first, the retraction of the face and loss of hair as it was observed after lesions of the cervical sympathetic in man.

Moebius contends that the true form of facial hemiatrophy, characterized by discoloration and wasting of the skin, discoloration and disappearance of the hairs, wasting of the bones and cartilages, differs entirely from the slight flattening of the cheek observed with disease of the cervical sympathetic nerve. On the other hand, Angelucci has seen very marked trophic disturbances follow extirpation of the stellate ganglion. He found that in new-born dogs and in adult cats defect of one stellate ganglion gave rise (on the side of the operation) to alopecia of the face, dystrophy of the cranial bones, and deficient development of the teeth. In adult rabbits and monkeys these conditions were not usually met with.

Dr. Collins and the writer observed in young cats, in which one stellate ganglion or one thoracic sympathetic nerve had been extirpated, the appearance of red, hairless spots, which later became scaly, psoriasis-like, and then turned pale, smooth, till finally they healed up entirely, becoming covered with a new growth of hair. The distribution of these patches seemed quite irregular and arbitrary in case of resection of the thoracic sympathetic nerve, although in case of removal of the stellate ganglion they were confined to the head, affecting, however, both sides of the latter.

Max Joseph (*Virchow's Archiv*, vol. 107, p. 119) operated on the second cervical nerve in young cats and extirpated a continuous portion, including a piece of both roots, the entire spinal ganglion, and a piece of the peripheral nerve. This operation evidently implies tearing off the ramus communicans of the nerve, and it is interesting to note that he also observed, on the faces of the animals, hairless spots such as we found. Of no less interest is the fact that when he cut both roots of the second cervical nerve without injuring the spinal ganglion or any part of the nerve trunk peripheral to the ganglion, the hairless spots did not appear. From this the inference seems justified that the trophic influence of the sympathetic efferent fibres of the ramus communicans is sufficient to prevent the loss of hair, since in the latter experiment the cerebro-spinal motor fibres of the ramus communicans were cut in their course through the anterior (and posterior?) roots, while the sympathetic efferent fibres were left untouched. Fig. 4576 makes these conditions clear.

The almost instantaneous changes in the biceps femoris and psoas muscles noted by Gaule in rabbits after lesion of the stellate ganglion, which changes he attributes to this lesion, are interpreted differently by Salvioli and Hering and need not therefore to be dwelt upon.

Angelucci has seen, in addition to the trophic changes referred to, interesting alterations in the eye follow extirpation of the stellate ganglion in new-born dogs—such alterations as lesser development of the circumference of the cornea and sclera, the eyeball showing a lessening of about 1 mm. in its diameters. Both in new-born dogs and in adult cats, a long time after the extirpation of the stellate ganglion, distinct dystrophies characterized by simple atrophy and sclerosis occur, especially of the texture of the iris and of the choroidea. In the iris of new born dogs the sclerosis of the tissue formed large plaques. The fundamental structure of the retina, however, was never found altered. Angelucci attributes the dystrophies reported, to changes in the blood-vessel walls, to which Vulpian and Giovanni had already called attention.

Floresco found that in rabbits section or resection of the cervical sympathetic nerves gave rise to an abundant production of fat tissue and to the hypertrophic development of the thyroid glands, the suprarenal bodies, the respiratory and digestive apparatuses, the heart, and the genital organs; while, on the contrary, the skin, the nervous and muscular systems, and probably also the osseous system became retarded in their development.

From all the facts mentioned, the important relation which the sympathetic nervous system bears to the trophic functions of the organism becomes highly evident.

(*b*) *Tonic Functions.*—It has been shown that many nerves of the sympathetic system are under the tonic influence of spinal or cerebral centres. Section of the cervical sympathetic nerve is followed by dilatation of the blood-vessels of the head; section of the abdominal sympathetic by dilatation of the blood-vessels of the hind paws; section of both splanchnics by the same phenomenon in the stomach and intestine. Severance of the nerves connecting the submaxillary ganglion with its encephalic centre gave rise to an unceasing continuous secretion of the submaxillary glands, proving the regulatory influence of the cerebro-spinal system upon the submaxillary ganglion (Claude Bernard). We recall further the experiments of Spallita and Consiglio, which showed that the tonus of the whole vascular system is kept up and regulated by means of the vaso-sensitive nerves.

Regarding the tonic influence of ganglia of the sympathetic itself, the views still differ. Tuwim claimed tonic effects of the stellate ganglion upon the pupil-dilating fibres, but such effects were denied by Schipiloff. We know, however, that the heart removed from the body still continues to beat, and that the bladder deprived of the motor nerves leading to it continues to perform its functions. It is quite questionable if the functions of maintaining tonus are different materially from the functions discussed under the heading of Vascular Functions (pages 584 and 585).

VII. Reflex Action of the Sympathetic System.—We have already mentioned some facts that point to a considerable functional independence of the sympathetic system apart from the spinal and cerebral centres. We remind the reader of the two facts regarding the independence of the bladder and of the heart functions mentioned at the end of the preceding section, and of the observations of Contejean, according to which the secretion of gastric juice continues after the stomach has been deprived of all its nerve connections.

This independence of the sympathetic system from the cerebro-spinal system is further demonstrated by the reflex action of sympathetic ganglia, which seems a fairly well established fact. Sokownin, Nussbaum, Nawrocki and Skabitschewski, and Langley and Anderson produced evidence that made such reflex action very probable for the inferior mesenteric ganglion.

Claude Bernard apparently established the fact of the reflex action for the submaxillary ganglion. François Franck claimed it for the ophthalmic (ciliary) and for the superior thoracic ganglion. The details cannot be discussed here.

VIII. The Functional Interrelation of the Sympathetic and Cerebro-Spinal Systems.—While, as has been shown in previous paragraphs, the sympathetic may to quite a degree functionate independently of the cerebral and spinal centres, its dependence upon the cerebro-spinal system is clearly shown by certain facts.

In this connection I recall Claude Bernard's observation of the paralytic secretion which occurs in the submaxillary gland after all nerve connections of the submaxillary ganglion with the cerebro-spinal axis are severed, and which finally leads to functional destruction of the gland. I also recall the fact that certain fibres or nerves of the cerebro-spinal system exhibit a marked tonus upon certain vegetative functions as well as upon the cerebro-spinal centres.

Space does not allow us to discuss here at length the nature of the relationship which exists between the sympathetic and the cerebro-spinal systems; we can only point out some principal facts. It is a characteristic of the vegetative functions, including in general the action of non-striated muscles, that while they can be stimulated to strong action by emotions—as evidenced by the blush of shame, the diarrhœa of fright, etc.—they cannot be influenced directly by the will. An exception to this rule was observed by Bechterew in a hysterical patient who by force of will could change the size of her pupil, and it is furthermore claimed by some persons that they can voluntarily arrest the action of their heart—an assertion which, it is true, still needs confirmation. However, on the whole, the rule holds good.

Another characteristic of vegetative or visceral functions is the fact that under normal circumstances visceral nerve stimuli do not rise to consciousness, although we do become conscious of them in case of increased visceral action; for instance, we feel palpitation when, owing to exertion, the heart beats with increased vigor and frequency, or in case of sensory hyperexcitability of central origin, such as occurs in hypochondriasis and neurasthenia. But even then the sensation is of a vague, indefinite character. This vagueness of visceral sensation is probably one of the factors preventing direct voluntary influence on vegetative functions. Another factor is probably the lesser excitability of the non-striated muscle as compared with that of striated muscle. A third factor might be sought in the manner of connection of the nerve endings in the vegetative organs with the parts which they supply (glandular cells, non-striated muscular fibres), and another one in the more numerously linked chain of neurones that has to be passed till a motor nerve impulse reaches a vegetative organ, as compared with the chain of fewer links to be passed by a motor impulse in the case of a voluntary striated muscle. (For further details consult the monograph of Onuf and Collins.)

General Physiological Remarks.—The essential influence which the sympathetic system exercises on the vegetative life of the organism has been amply demonstrated in the foregoing review. Inasmuch as some vegetative functions are exquisitely vital, we may say also that the sympathetic system possesses in high degree vital functions. This is confirmed by the fact that in very young cats lesions of the important parts of the sympathetic invariably proved fatal. Even if the animals outlived such operations as extirpation of the semilunar ganglion or removal of the stellate ganglion or resection of the lower part of the thoracic sympathetic, they invariably died, and usually a few hours or days after the operation (Onuf and Collins).

The death of many animals during the operations was caused by pulling upon the sympathetic nerve or by bruising a sympathetic ganglion. This was especially the case in operating to remove the stellate ganglion. Although the animal would be breathing vigorously and freely immediately before, as soon as the stellate ganglion was pulled upon or as soon as its connections with the thoracic sympathetic nerve were severed, respiration suddenly became arrested and the animal promptly died.

Older animals—that is, cats which had reached the age of five or six weeks—stood these lesions much better, and three of them lived for from three to five months after the operation, when they were killed.

In man the upper cervical ganglion of the sympathetic has been frequently removed of late for the relief of glaucoma, and no deleterious effects on the heart action or respiration were noted. However, the patients thus operated upon were usually adults.

A fact recently brought out by Cleghorn deserves mention here. Cleghorn found that glycerin extracts of sympathetic ganglia, when injected into the femoral or jugular vein, caused a fall in blood pressure which was not observed if glycerin extracts of spinal ganglia, or of spinal cord or brain matter, or of nerve or abdominal tissue, were injected instead. Cleghorn seems recently to connect this vascular effect of the glycerin extracts of sympathetic ganglia with the presence in the latter of large polygonal cells, discovered by Stilling, which cells stain deeply in chromic acid and are found also in the suprarenal capsules.

In concluding this subject, attention is called once more to the remote effects of lesions of the sympathetic, these being often late in their appearance and showing a tendency to progression, as was the case with the digestive and respiratory disturbances following removal of the stellate ganglion or of part of the thoracic sympathetic nerve.

Representation of the Sympathetic in the Spinal Cord and Brain.—The rôle of the rami communicantes and their homologues, in establishing a connection between the cerebro-spinal and sympathetic systems, has been amply discussed in previous paragraphs (see pages 580 and 581). It remains now to describe in detail the manner of representation of the sympathetic in the spinal cord and brain.

From a study of the degenerations following resection of portions of the gangliated cords, Dr. Collins and the writer (see the monograph above mentioned) came to the following conclusions regarding the course and spinal representation of the afferent and efferent fibres of the sympathetic nerve proper in the cat:

1. Most, or at least many, of the afferent (sensory) fibres of the sympathetic nerves do not originate from cells of the spinal ganglia, as Kölliker claims, but must have their cells of origin within the ganglia or plexuses of the sympathetic system.

2. The chief terminal station for the afferent fibres of the sympathetic is *Clarke's column*, the said fibres probably ending there around the cells of this column. Other terminal stations of such fibres are probably the lateral horn and the zone between the anterior and posterior horns which we called the intermediate zone. The fibres probably terminate around the large cells of these regions.

3. Clarke's column, besides being a terminal station for afferent fibres from the vegetative organs, may be instrumental also in conducting sensory stimuli from the muscles, tendons, joints, and bones to the cerebellum, being thus largely concerned in maintaining equilibrium.

4. The afferent fibres of the sympathetic nerve after entering the spinal cord probably send reflex collaterals to the nuclei of the efferent fibres of the sympathetic (see Fig. 4581).

5. The afferent fibres of the *lumbar* sympathetic nerve, entering the spinal cord by way of the posterior roots, after having arrived at Clarke's column, evidently describe a longitudinal course upward (cephalad) to terminate around cells of a considerably higher level (see Fig. 4579).

6. The afferent fibres coming from the ganglia of the lower half of the thoracic sympathetic take on the whole a rather horizontal course in the spinal cord, to become connected with spinal cells of the same level, but part of these fibres probably descend either in the spinal cord or in the sympathetic nerve through the distance of one or more segments before reaching the cells around which they terminate. This is illustrated diagrammatically in Fig. 4580.

7. Many of the afferent fibres derived from the stellate ganglion probably make a long descent in the spinal cord or possibly in the sympathetic nerve, becoming connected partly with the same cells with which the fibres from the lower portion of the thoracic sympathetic nerve form connections (see also Fig. 4580).

8. The efferent (motor, secretory, inhibitory, etc.) fibres of the sympathetic probably take their origin from the cells of the following cell groups of the spinal cord: (*a*) The paracentral group; (*b*) the small cells of the lateral horn; and (*c*) probably the small cells of the zone situated between the bases of the anterior and posterior horns (intermediate zone). The situation of these groups is diagrammatically illustrated in Fig. 4581. That most (or all) of these fibres do not pass uninterruptedly to the peripheral organ innervated by them, but terminate in some ganglion of the sympathetic, and that from there a new set of neurones originates, giving rise to "sympathetic" fibres which pass to the periphery, has been discussed in other paragraphs, chiefly pages 580 and 581.

9. The paracentral group has possibly a vascular function.

10. The pathway of the efferent fibres of the sympathetic is probably similar to that of the afferent fibres as outlined under 5, 6, and 7; with this difference, that most of them pass through the anterior and not the posterior roots, and that they conduct the impulse in the opposite direction to that of the afferent fibres.

11. The spinal representation of both the afferent and the efferent fibres of the sympathetic nerve is probably bilateral.

12. The homologon of Clarke's column for the oblongata is probably a large-celled nucleus accompanying the so-called solitary or respiratory bundle at its ventro-lateral border.

13. The homologon of the paracentral group for the oblongata is evidently the so-called dorsal vagus nucleus, called also vagoglossopharyngeal nucleus, situated at the floor of the fourth ventricle.

It probably has the function of supplying the non-striated muscles innervated by the pneumogastric nerve, while those nerve fibres of this nerve which supply striated muscles probably originate from the nucleus ambiguus.

The relations between: (1) the ninth, tenth, eleventh nerves, (2) solitary bundle, (3) vagoglossopharyngeal nucleus, and (4) nucleus ambiguus are illustrated in Fig. 4582.

14. Higher up in the cerebral axis the paracentral group (of the spinal cord) is possibly and even probably represented by the vesicular cells accompanying the so-called cerebral fifth root (known formerly under the name of the descending fifth root) and by the cells of the substantia ferruginea.

To the views arrived at by Gaskell by a most ingenious method we can only allude here, giving his conclusions as to the centres for the efferent fibres (including those of the sympathetic) in the form of a table:

A. (Cells of the anterior horns.) Nucleus of efferent nerves to somatic muscles.	Represented in the medulla oblongata by the hypoglossal nucleus.
B. (Large cells of lateral horns.) Nucleus of efferent nerves to striated splanchnic muscles.	Represented in the medulla oblongata by the nucleus ambiguus (motor vagus nucleus).
C. (Cells of Clarke's columns.) Nucleus of anabolic (inhibitory) nerves to splanchnic glandular system and to muscles of viscera.	Represented in the medulla oblongata by the nuclei at the floor of the fourth ventricle, known as the accessory and the dorsal vagus nuclei.
D. (Solitary cells of posterior horn.) Nucleus of motor nerves to muscles of viscera.	No mention made respecting their possible representation in the medulla oblongata.
E. (Small cells of lateral horn.) Nucleus of katabolic (motor) nerves to splanchnic glandular system and to muscles of vascular system.	

This shows that in many respects Gaskell had come to conclusions similar to those reached by Dr. Collins and the writer.

To enter on the conclusions of other workers in this field, for instance Mott, the space allotted to this subject does not allow. *B. Onuf (Onufrowicz).*

SYMPATHETIC NERVOUS SYSTEM, DISEASES OF. (GENERAL.)—A systematic discussion of the diseases of the sympathetic nervous system is, at the present state of our knowledge, not feasible. The anatomy, physiology, and pathology of this part of the nervous system are still quite obscure.

At the bedside symptoms referable to and explicable by disordered function of the vegetative neural mechanism are encountered quite frequently. These symptoms are mainly expressions of exaggerated, diminished, or perverted trophic, circulatory, secretory, viscero-sensory, and viscero-motor functions.

Diseases of the sympathetic nervous system may be divided into two large groups:

1. Primary (idiopathic).
2. Secondary (deuteropathic).

Many general diseases were, and some are still, looked upon as expressions of primary functional or structural derangement of the sympathetic nervous system. Such are, for example, migraine, angioneurotic œdema, Basedow's disease, facial hemiatrophy, erythromelalgia, scleroderma, Raynaud's disease, and Addison's disease. These and other trophic syndromes are frequently interpreted as primary diseases of the sympathetic nervous system.

The familiar syndrome of irritation or paralysis of the cervical sympathetic is a good illustration of a secondary affection. Very little is known of primary or secondary diseases of the thoracic part of the sympathetic chain. Oppenheim records a case which presented during life a unilateral œdema, the explanation of which was found in an abscess near the thoracic vertebral column. The writer published a case of abscess formation implicating the thoracic chain of the sympathetic, which presented rather obscure symptoms during life (*Med. Rec.*, June 16th, 1900).

The rôle that diseases of the thoracic part of the sympathetic chain may play in the pathology of asthma and cardiac neuroses is entirely unknown.

The relation of the abdominal sympathetic to the pathogenesis of Addison's disease, diabetes, colica mucosa, is still under discussion. Symptoms referable to disorder of the functions of the sympathetic nervous system are frequently accompaniments of almost any organic lesion of the cerebro-spinal nervous system.

The gastric and other visceral crises arising in the course of tabes, the trophic manifestations accompanying this disease as well as syringomyelia, are good illustrations in point. *Joseph Fraenkel.*

SYMPATHETIC OPHTHALMIA includes two quite distinct diseases—sympathetic inflammation, or sympathetic ophthalmitis; and sympathetic irritation. These conditions are liable to arise in a previously healthy eye, after the fellow-eye has been injured and has become the seat of chronic inflammation due to such injury. In addition to these two definite forms of disease, to be described below, there are cases in which a blind degenerated eye seems to exert an unfavorable influence upon the fellow-eye.

Many surgeons believe that any blind and degenerated eyeball should be removed, if the fellow-eye becomes impaired by chronic progressive disease. Thus, if one eye presents an absolute glaucoma and the other a beginning glaucoma, the prospect of arresting the process in the latter may sometimes be improved by removing the blind eye. Or if one eye be blind with general detachment of the retina and softening of the globe, it is thought that choroidal degeneration or cataract affecting the other may be favorably influenced by removal of the blind eye. Such a belief in the dangers of sightless, degenerated eyeballs is not universal and should not be acted upon unless there is some evidence of disease in the second eye or danger of sympathetic inflammation. But if other disease of the better eye arises, the possibility of influencing it favorably by removal of a sightless degenerated stump should be carefully considered.

It is possible that in some cases inflammation of the uveal tract not caused by injury may extend from one eye to the other. But this is not certainly established. It is convenient to speak of the injured and primarily inflamed eye as the *exciting eye*, and of the other as the *sympathizing eye*.

Sympathetic Ophthalmitis.—(Synonyms: Sympathetic uveitis, Cyclitis, or Irido-cyclitis, Malignant Uveitis, or Migratory Ophthalmia.) This is an inflammation involving chiefly the uveal tract of the eye, but liable to extend to all the tissues of the eyeball, running a chronic course marked by repeated relapses, and ending in the majority of cases in complete blindness.

Causes.—Sympathetic inflammation is caused by non-purulent traumatic inflammation in the uveal tract of the fellow-eye. Injury of one eye unattended with uveal inflammation of the injured eye does not cause sympathetic uveitis. Uveal inflammation not due to traumatism does not excite this disease. Injuries to the eyeball, which are followed by severe purulent uveitis or panophthalmitis, are not likely to excite sympathetic inflammation. Disease in other organs may cause metastatic inflammation of the eye, but not the form of inflammation now under consideration. The character of the wound of the exciting eye greatly influences the liability to sympathetic disease.

The lodgment of a foreign body within the eyeball constitutes the most dangerous form of injury, unless the eye be promptly destroyed by suppuration. Yet the character of the foreign body and the structure in which it is lodged modify its evil influence. Minute aseptic foreign bodies sometimes remain in the eyeball indefinitely, without causing serious impairment of the injured eye or danger of sympathetic ophthalmia in its fellow. They are least dangerous when lodged in the crystalline lens or in the corneo-scleral coat. They are most dangerous when suspended in the vitreous or embedded in the ciliary processes or choroid. Comparatively small or punctured wounds are more to be feared than extensive cuts or lacerations.

Wounds that pass through the anterior chamber are less dangerous than those which enter through the sclera directly into the vitreous. When the body which inflicts the injury reaches the eyeball only after passing through the lid, the danger is lessened. Wounds attended with free hemorrhage or an abundant flow of aqueous humor are less dangerous. Wounds in the ciliary region have long been recognized as especially dangerous. They are made by bodies which have not passed through the lids. They enter directly into the vitreous chamber. The track of the wound is likely to be obstructed by a prolapse of the ciliary body into it or by swelling of the injured margin of the lens. These wounds, furthermore, involve the most complex and functionally active part of the uveal tract. However, any perforating wound of the sclero-corneal coat, even the incision of a smooth, clean operation, may be followed by sympathetic ophthalmitis. Perforations of this coat by disease, as by corneal ulcer, may also cause it. Cases are reported in which injury without perforating wound, such as bruise of the eyeball with dislocation of the crystalline lens, has given rise to sympathetic ophthalmia. But it is not certain that such injuries cause sympathetic uveitis.

The form of inflammation after injury, which makes an eyeball dangerous to its fellow, is a plastic uveitis. In its typical form it is characterized by marked involvement of the ciliary body, prolonged pericorneal redness, tenderness of the ciliary region, punctate deposits on the back of the cornea, diminished tension of the eyeball, and shrinking of the globe. There are also apt to be marked involvement of the iris, posterior synechia, alteration of color or appearance from degenerative changes, and with these more characteristic symptoms may occur changes in any part of the globe. Sight is usually entirely lost.

But it must be remembered that in rare instances the changes in the exciting eye may be comparatively slight yet equally dangerous. In numerous cases sympathetic ophthalmitis has been excited by an eye which retained useful or even good vision. The redness and ciliary tenderness may be transient, the diminution in the tension of the eyeball but slight, and the changes in the iris and deposits on the cornea barely perceptible, and still sympathetic uveitis may arise and destroy the other eye. On the other hand, free suppuration is not sure to prevent an eye from exciting sympathetic ophthalmitis. Neither is mechanical traumatism essential An eye that has had the cornea perforated by an ulcer, especially if this has been followed by prolapse of the iris, or an eye that contains a tumor, especially sarcoma or glioma, may also be the seat of a uveal inflammation that will cause sympathetic ophthalmitis All eyes, the coats of which have been perforated either by mechanical violence or by ulceration, must be objects of suspicion.

Premonitory Symptoms.—Previous to an outbreak of sympathetic ophthalmia, the exciting eye is noticeably red and tender. Either it has failed to become entirely quiet or symptoms of irritation and inflammation have reappeared. In the sympathizing eye there may be undue sensitiveness to light, decided loss of the power of accommodation, and quick tiring of the eyes with ordinary use. Symptoms of this kind should be watched for, when there is reason to fear sympathetic ophthalmia, and their presence should excite alarm. But they cannot be wholly relied upon to foretell an outbreak of sympathetic inflammation They may be so slight as to occur unnoticed, or all of them may be absent.

Symptoms and Course of the Disease.—The actual beginning of sympathetic inflammation is insidious. Slight photophobia, increased lachrymation, or a little redness of the eye is noticed. But it is difficult to fix the exact time at which it began As happens with other forms of uveitis, the hyperæmia may at first seem general, involving the conjunctiva as much as the pericorneal or deep scleral vessels. There may be slight discoloration of the iris and sluggishness in its reaction to light, or even one or two minute posterior synechiæ, by the time it is realized that the eye is inflamed. A little impairment of vision and faint haziness of the dioptric media may be present at the first examination.

From day to day the symptoms of uveitis become more severe and unmistakable. The lachrymation becomes excessive, the pericorneal and deep redness predominate. The photophobia becomes severe, the iris assumes the greenish or brownish tint of iritis, loses its lustre, and becomes distinctly thickened. It yields slowly and imperfectly to a mydriatic. The posterior synechiæ become more numerous and broader. The vitreous grows noticeably cloudy and the vision is greatly impaired. Points of tenderness appear in the ciliary region, and the tension of the eyeball is perceptibly diminished. There may be the severe pain of an acute iritis, but generally the pain is not great as compared with the tenderness, photophobia, and impairment of vision.

After a period of from two to six weeks the symptoms cease to grow worse, and some days later improvement is noticed. The pain and photophobia become less and vision may slightly improve. But some hyperæmia and ciliary tenderness remain, and after a remission, which may vary from a few days to several months, all the symptoms grow worse again, vision sinks lower than it has been before, the media become more obscured, and the tension of the eyeball still further diminished. Other remissions and relapses may occur, and it may be two or three years before the eye reaches its final condition of complete blindness, with greatly lowered tension, degenerated iris, and shrinking of the globe. The retina, vitreous, and lens directly suffer from the disease of the nutritive coat of the eye. The lens and vitreous become opaque. The latter shrinks and the retina becomes detached and completely altered. The cornea, besides the deposits of opacity on its posterior surface, becomes more or less opaque and shrunken. This condition may be reached in a few weeks, before the first remission has occurred, the subsequent relapses being marked merely by increased pain, soreness, and hyperæmia in the sightless and shrunken eyeball.

Atypical Cases.—The course of the disease as altered by treatment will be discussed under that head. In a few cases impairment of vision is at first the only symptom noticed. Ophthalmoscopic examination reveals hyperæmia, haziness, and slight swelling of the head of the optic nerve, with haziness and change of color, and perhaps swelling of patches of the choroid and retina. Cases of this kind usually develop later the more characteristic symptoms of sympathetic uveitis. They have been described as cases of sympathetic neuro-retinitis. But they are probably essentially uveal, the choroid being at first chiefly affected

As with other forms of uveitis, structures outside the uveal coat, and not directly dependent on it, are liable to be involved. Quite apart from the usual deposits on the posterior surface and the opacity due to degeneration, the cornea may be early affected with interstitial or ulcerative inflammation; or severe conjunctivitis may be present. So prominent are these complications in certain cases that they have been reported as cases of sympathetic keratitis or conjunctivitis. But in all cases in which the sympathetic character of the disease can be regarded as demonstrated there has also been distinct evidence of uveitis.

Diagnosis.—The symptoms presented by the sympathizing eye are not in themselves a sufficient basis for the positive diagnosis of sympathetic ophthalmia. They are merely those of a severe uveitis which tends to become chronic, to relapse, to go on to complete blindness and degeneration of the eyeball. This uveitis is especially insidious in its manner of beginning and progress, and it exhibits a special tendency to cause great diminution in the vision and in intraocular tension. But these features are not alone sufficient to distinguish it from other forms of uveitis. The history of traumatism and uveal inflammation of the other eye are essential to the diagnosis; not traumatism alone, for this does not cause sympathetic disease, unless it has been followed by uveal inflammation.

The time which has elapsed since the injury must also be considered. Sympathetic inflammation rarely if ever arises within three weeks from an injury. Usually the interval is six weeks or more. On the other hand, it rarely begins more than two or three months after the injured eye has become entirely quiet and free from inflammation. Cases beginning more than six months after the exciting injury are unusual, and more than a year afterward are quite rare. Still a few cases are recorded in which the exciting eye has remained quiet for many, sometimes thirty or forty, years before causing an outbreak of sympathetic ophthalmitis. Eyes that have been so long injured are more apt to cause sympathetic irritation. The diagnosis between these two conditions will be considered in connection with the latter.

An attack of iritis or other form of uveitis occurring years after an injury to the other eye should not be regarded as necessarily one of sympathetic inflammation, although that should be suspected. If the injured eye remains free from tenderness and irritation, even though it be entirely blind, and especially if its tension is normal or nearly so, and the attack does not show the special characteristics of sympathetic uveitis, the case is probably not one of sympathetic disease.

Pathology.—The anatomic changes which mark sympathetic ophthalmia are those of plastic uveitis. There are exudates which become organized into connective tissue, which may in time ossify, while the characteristic elements of the ocular tissues degenerate and atrophy. But although the transmission of disease from one eye to the other has been observed with especial interest for two hundred years, the method of transmission is still unknown. Mackenzie, in 1844, suggested transmission along the optic nerve. Müller, in 1858, suggested transmission by the ciliary nerves. A morbid functional activity was assumed, a reasonable hypothesis to explain sympathetic irritation, which was then confused with sympathetic inflammation. In 1881 Snellen argued that this was a specific inflammation, caused by organisms transmitted through the lymph spaces of the optic nerves. Berlin suggested that micro-organisms causing it might be carried to the exciting eye by the blood current, and find conditions suitable for their development only in the uveal tract of the sympathizing eye. Deutschmann claimed to have produced sympathetic ophthalmia in the rabbit, and to have demonstrated its extension along the optic nerve. Gifford and others failed to confirm his experiments, and showed that the probable explanation of his results was a general infection rather than a sympathetic ophthalmia. Randolph, using dogs, which are less liable to general infection, found that the fellow-eye was unaffected. Finally, it has been suggested that reflex influences through the ciliary nerves may prepare the uveal tract of the sympathizing eye for the invasion of organisms reaching it through the circulation.

That nerve influences starting from the exciting eye may powerfully affect the sympathizing eye is demonstrated by sympathetic irritation and its immediate relief by the removal of the exciting eye. It is equally certain that such nerve influences do not alone cause sympathetic ophthalmitis. In this disease some other factor must be added. Infection with a distinct period of incubation is the factor that best accords with our present ideas of such inflammations. The period of incubation may cover the two or three weeks that always elapse between injury of the exciting eye and sympathetic ophthalmia, or during which sympathetic inflammation is liable to occur after the removal of the exciting eye.

Prevention.—With a disease which tends to cause complete blindness, and which often goes on to this termination in spite of all treatment, prophylaxis is of the highest importance. In timely enucleation of the injured eye we have a certain preventive. The only questions that arise in connection with it are: In what cases should it be applied, and have we any other equally or sufficiently reliable prophylactic?

It cannot be said in any case of injury that enucleation is demanded to prevent sympathetic disease until a plastic uveitis has been set up. But with regard to an eye known to contain a foreign body of more than the most minute size that cannot be extracted, it may be assumed with almost absolute certainty that such dangerous uveitis will occur; and if an eye be so injured that future vision with it is impossible, immediate enucleation will so shorten the period of disability that it will often be justified. When the eye has become the seat of uveitis due to injury, and the inflammation does not begin to subside within three or four weeks, especially if the tension of the globe is much below normal, if blind it should be promptly enucleated. If not blind, but with vision no longer useful and diminishing, the eye should be enucleated if the patient cannot remain under observation. If the eye be blind with greatly diminished tension from an injury that has occurred within two years, even though it be free from hyperæmia or tenderness, it should be enucleated if the patient cannot remain within reach of competent professional assistance. The location of a wound in the ciliary region is an added reason for enucleation. Any blind eye that is known to contain a foreign body should be enucleated.

None of the substitutes for enucleation are so certain to prevent sympathetic inflammation. They have a field of usefulness, but not for this purpose. Nevertheless, if a patient absolutely refuses enucleation, but will allow evisceration, it may be proper to do the latter operation rather than decline further care of the case. In doing evisceration the sclera should be freed from all remains of its contents and mopped with a strong germicide, as carbolic acid or a solution of formaldehyde.

Enucleation of an injured eye does not instantly confer immunity from sympathetic uveitis. In a good many cases the inflammation has appeared within two or three weeks after the removal of the exciting eye, and in a few cases as late as four weeks. But almost invariably sympathetic inflammation arising in this way has yielded to treatment and has ended in recovery.

Treatment.—The first step is removal of the exciting eye. The only exception is when the exciting eye retains useful vision. There are a number of cases on record in which the sympathizing eye became entirely blind, while the exciting eye retained useful vision for many years or throughout life. It has sometimes been thought that removal of the exciting eye was followed by increased violence of the sympathetic inflammation. But probably this was nothing more than the increase observed when the exciting eye was not disturbed. On the other hand, the cases in which the exciting eye has been removed especially if removed early, show a much larger proportion of recoveries than do those in which the exciting eye was allowed to remain. The strong tendency to recovery in cases of sympathetic inflammation arising after enucleation also attests the value of this measure.

The sympathizing eye should be placed under the influence of atropine as soon as possible. A strong solution, two per cent., may be instilled, one drop every ten minutes for an hour; or after the use of cocaine a small crystal of atropine sulphate may be placed in the conjunctival sac, near the external canthus. Until this crystal is dissolved, or while instilling the strong solution, we should guard against atropine poisoning by everting the lachrymal puncta through traction on the skin at the side of the nose, and holding in contact with them a little absorbent cotton, thus keeping the atropine solution from getting into the tear passages. After this first mydriatic attack the strong solution of atropine should be instilled two or three times a day.

Before each instillation of atropine, or at more frequent intervals if the eye is painful, it should be bathed with very hot water, not longer than five minutes at a time. Dry heat, best from the electric coil, may be applied for periods of one half hour to two hours. If the hyperæmia is severe, and especially if there is pain, one or two fluidounces of blood may be taken by leeches or by the artificial leech applied to the temple. Subconjunctival injections of physiologic salt solution may be made at intervals of two or more days. These should be placed rather deeply within the capsule of Tenon. On going out in daylight the eye should be protected by very dark glasses or an opaque shade; but it should not be kept continuously covered by thick dressings.

As in other forms of uveitis, general treatment is of great importance. Mercury should be given freely up to the point of causing tenderness of the gums or other evidences of its poisonous action. At first, calomel may be given until it acts as a purgative, with large inunctions of mercurial ointment twice daily. Later, any form of mercurial that will sustain the mercuric influence without symptoms of poisoning may be employed. Nothing will be gained by carrying the action of mercury beyond the point indicated. But its administration should be continued until all symptoms of inflammation have disappeared.

Next to mercury, the most important drug is sodium salicylate. This should be given in the largest doses that will be tolerated; from twenty to forty grains, three or four times a day, in an adult. But such doses need not be continued more than a few days. Later, it may be given in smaller doses or discontinued. Should this drug cause serious disturbance of the stomach, other salicylates or aspirin may be substituted. For a chronic case or at a later stage, the iodides may be beneficial.

It is very important that the patient should be kept in as good a state of general health as possible. On this account the administration of mercury and the salicylates must be closely watched. The patient must not be confined to a dark room. The use of alcohol in any form should be forbidden. Diet and rest must be carefully attended to, and general tonics, especially iron, may be indicated. After apparent cure the patient should be kept under observation, and should avoid excessive use of the eyes or indulgence in alcoholic drinks for many months.

When the attack of inflammation has been finally subdued, it may leave the pupil closed by exudate, with or without an opaque lens. This condition might require for its relief an operation, but the eye should be allowed to remain quiet for years before any such operation is attempted. If done within a year or two after the inflammation has subsided, it will almost certainly cause a recurrence of the disease. Nothing will be gained by the attempt, and much will be lost.

Prognosis.—Sympathetic inflammation, untreated, ends in blindness; and, if those cases which arise after the enucleation of the exciting eye be excluded, probably less than half can be cured by treatment. The nature of the injury or the violence of the inflammation in the exciting eye has little influence over the prognosis when once sympathetic disease has actually occurred. Attacks beginning with lesions in the fundus show a rather better proportion of cures than those commencing with marked iritis. The first remission must not be mistaken for a cure. But when recurring exacerbations grow less severe and the sight is left no worse by them, an ultimate cure with partial or complete restoration of vision may be hoped for. Not until the eye has been free from inflammation for a year should the case be considered cured.

SYMPATHETIC IRRITATION, OR SYMPATHETIC NEUROSIS.—This is a condition set up by disease in the fellow-eye and characterized by extreme irritability, photophobia, excessive lachrymation, moderate general hyperæmia, and inability to use the eye, sometimes equivalent to complete temporary blindness.

Cause.—This is disease in the fellow-eye, generally of long standing and marked by very extensive degenerative changes. The exciting eye may show no symptoms of present inflammation, no hyperæmia or tenderness. Its condition may be the result of injury, or it may be the result of disease quite independent of traumatism. Intra-ocular tumor, without perforation of the ocular coats, may cause it. Ossification of the choroid is a quite common cause.

Symptoms.—It begins with inability to use the eyes for ordinary work, photophobia, and increased lachrymation. The symptoms vary in severity from time to time, but tend on the whole to grow worse, until any use of the eyes becomes impossible. On close examination the cornea will be found free from deposits, the pupil small but reacting well, the iris normal; and if photophobia does not prevent an ophthalmoscopic examination, the media are found clear and the fundus is normal. The hyperæmia is quite general, may disappear when the eye is kept quiet in a dark room, but increases rapidly on attempting to use the eyes or even with examining them.

Diagnosis.—Sympathetic irritation has to be distinguished from eye strain and from sympathetic inflammation. Hyperopia, astigmatism, or presbyopia may cause apparent lack of accommodation, excessive irritability of the eye, lachrymation, photophobia, and difficulty with near work. Therefore the refraction and accommodative power should be carefully measured before adopting the diagnosis of sympathetic irritation, even though the fellow-eye presents all the conditions that would make it the cause of this neurosis. By placing the suspected eye under the influence of a mydriatic, eye strain can be excluded.

To differentiate between sympathetic inflammation and sympathetic irritation is often of great practical importance. Their chief points of difference may be contrasted as follows:

Inflammation.	*Irritation.*
1. Follows perforation of the sclero-corneal coat, usually by traumatism, especially if the wound is in the ciliary region or if a foreign body is lodged in the eye.	1. Follows extensive degeneration of the fellow-eye, with or without traumatism, especially if the eye contains a foreign body or new-formed bone.
2. Occurs at from three weeks to six months after injury; is rare after one year.	2. Occurs usually many years after injury, or disease, of the exciting eye.
3. The exciting eye is almost always red or sore before the outbreak.	3. The exciting eye may be entirely quiet and free from irritation.
4. There are deposits on the posterior surface of the cornea, the iris is discolored, its reaction impaired. There are posterior synechiæ; the vitreous is hazy; vision is permanently diminished.	4. The cornea is free from deposits, the iris normal; the vitreous clear, and the eye may for a short time be capable of normal vision.
5. There are always marked organic changes.	5. There are no organic changes.
6. There are relapses at intervals of many days, weeks or months.	6. The severity of the symptoms may vary from hour to hour.
7. It terminates in slow recovery under treatment; or, more frequently, in complete blindness.	7. It tends to continue indefinitely; but ends in immediate restoration to normal after removal of the exciting eye.

The differential diagnosis is only difficult at the outset before the organic changes of sympathetic inflammation have had time to occur.

Pathology.—No anatomical changes occur, and the morbid influence is undoubtedly transmitted from the exciting to the sympathizing eye through the ciliary nerves.

Prevention is of little importance. The only effectual preventive measure is removal of the eye that is liable to cause it, and this is equally efficient after the condition of sympathetic irritation has actually developed. And since a degenerated eyeball may be retained many years without causing sympathetic irritation, the possibility of that event at some future time does not justify enucleation.

Treatment.—This is enucleation of the exciting eye or one of the substitutes for enucleation. Where sympathetic irritation alone is to be feared, probably evisceration or even optico-ciliary neurotomy will be as efficient as the removal of the eyeball. If preferred by the patient or operator, resort to one of them, preferably evisceration, in place of enucleation, is entirely proper. If the patient strenuously objects to operation and the case is clearly not one of sympathetic inflammation, palliative measures may be tried. Avoidance of close work and keeping the eye under a mydriatic, as atropine sulphate 1, distilled water 100, instilled twice a day, will often give partial or temporary relief. The internal administration of bromides is also useful. In a few cases freedom from irritation is thus secured, and it may last for months or years. But in nearly all cases the return of the symptoms, and the continual annoyance and disability which they cause, will in time overcome the strongest objections to operative treatment.

Prognosis.—Without treatment the irritation continues or recurs indefinitely. With removal of the exciting eye the prognosis is entirely favorable. Donders reported a case in which the patient had believed himself entirely blind for two years, but was proved to possess normal vision two hours after the removal of the exciting eye.

Edward Jackson.

SYMPHOROL-SODIUM, SYMPHOROL-LITHIUM, and **SYMPHOROL-STRONTIUM** are the respective caffeine sulfonates of these metals. They are white, odorless, and bitter, are readily soluble in water, except the sodium salt, and are insoluble in ether, benzol, or chloroform. These salts are strongly diuretic in dosage of 1–4 gm. (gr. xv.–ʒ i.) a day, and are claimed to retain the diuretic effect of the caffeine without its stimulating action on the heart and nervous system. The sodium salt is in common use under the simple term "symphorol."

SYNCOPE. See *Brain Diseases: Anæmia.*

SYNCYTIOMA.—(Synonyms: Deciduoma malignum, Sarcoma uteri deciduocellulare, Chorionic epithelioma, Choriocarcinoma, Syncytioma malignum, and Carcinoma syncytiale.)

Under syncytioma are to be considered those new growths which consist largely or in part of syncytium such as is found covering the chorionic villi. In order to understand clearly the relation and origin of this class of tumors, it is necessary to have a knowledge of the placenta and its development. Of especial importance in this relation is the development of the chorionic villi. The villi are at first clothed with fœtal ectoderm, which, we have reason to believe, becomes two-layered in early embryonic life; the inner layer, the "cell layer" of Langerhans, being composed of separate individual cells with large vesicular nuclei and reticular protoplasm; the outer, or "syncytial" layer, being composed of a continuous mass of dense, deeply stained protoplasm containing smaller nuclei than the preceding layer. The syncytium resembles not a little a huge giant cell. In tumors of this group both the syncytium and the cell layer of Langerhans are usually represented in varying proportions. The origin of the syncytium has long been a matter of dispute, some observers maintaining that it is derived from the epithelium of the uterine mucosa, while others believe that it arises by delamination from the ectoderm covering the ovum. A study of preparations of developing placentas furnishes convincing evidence that the uterine mucosa takes no part in the formation of the syncytial layer. The close relation of the syncytium to the cell layer of Langerhans and the presence of transitions between the two make it clear that the syncytium arises from the fœtal ectoderm.

From the above observations it would appear that a syncytioma is to be regarded as a malignant form of new growth originating from fœtal ectoderm. In the discussion of these tumors the term "syncytium" applies only to a special tissue, identical with or closely resembling the so-called syncytial layer of the chorionic villi. Syncytia other than this special form have no relation to the tumors in question.

Syncytiomata may be divided into two groups:

1. Certain rare cases of teratomata in which a syncytium develops.

2. Those tumors arising in the uterus after pregnancy to which the terms "deciduoma malignum," "syncytioma malignum," etc., have been applied.

Several teratomata of the testicle have been recently described in which a portion of the growth resembles in every respect a true syncytioma of the uterus. Such growths are described by Carey, Wlassow, and Schlagenhaufer. The syncytium in these teratomata represents one of the many lines of tissue differentiation found in these neoplasms, and, from morphological characteristics as well as on theoretical grounds, it may be considered as homologous to the true chorionic syncytium. Teratomata in which the syncytium forms a large portion of the tumor appear to possess a considerable degree of malignancy; for example, metastases have been described as well as a tendency of the growth to infiltrate surrounding tissues. On account of the rarity of syncytial growths associated with teratomata, and since they comprise only a portion of these neoplasms, they are here given but brief mention. Concerning the further characteristics and the theories of origin of teratomata, one should consult monographs on that subject.

DECIDUOMA MALIGNUM.—*Historical.*—The term deciduoma malignum was first applied by Sänger in 1888 to a peculiar malignant growth of the uterus with metastases following an abortion. Although this term is considered to be a misnomer, it is generally deemed advisable, on account of the multiplicity of terms, to retain, for clinical usage at least, Sänger's original terminology. Sänger believed that the tumor in his case consisted of decidual cells, and he placed it among the sarcomata. Following this and quite independently of Sänger, Pfeiffer described a case and also applied the term deciduoma malignum. In 1893 Sänger published a monograph which comprised all that was then known of this subject. In 1895 Williams and Marchand published monographs. Williams, after reviewing the literature, came to the conclusion that in the various cases reported there is some variation in the nature of these tumors, that is, that some consist for the most part of decidual cells and are thus of maternal origin, others consist of tissue analogous to the syncytium and Langerhans' cell layer and are of fœtal origin, while it is not improbable that others are of both maternal and fœtal origin.

Marchand believed that both the syncytial and the cellular portions of these tumors are of fœtal origin. A great many cases have been reported since the publications of Williams and Marchand. Ladinski, in 1902, was able to collect one hundred and thirty-two cases. Such is the comparative frequency of their occurrence that they are worthy of consideration to the clinician in cases of uterine hemorrhage.

Occurrence.—Deciduoma malignum may occur at any time during the child-bearing period. That it may not be discovered until after the menopause is shown by a few cases. It is always associated with pregnancy, appearing after a full-term labor, an abortion, or the expulsion of a hydatidiform mole. It is evident that in certain cases the tumor has begun to develop before the expulsion of the mole. The frequent association of this tumor with vesicular moles is to be noted. Dorland, in a series of fifty cases of deciduoma malignum, found that twenty-two cases (43.3 per cent.) gave a history of the expulsion of a mole at some time prior to the appearance of the growth.

Gross Appearances.—Metastases of the growth are often found in the vaginal wall. They appear as soft, vascular nodules, friable, often necrotic and ulcerated, and sometimes protruding from the vulval orifice. The cervix is usually soft and enlarged from the preceding pregnancy. On opening the uterus the primary growth will usually be found bulging from some part of the uterine wall. It varies in size and form, is reddish in color, sometimes mottled with gray. The primary growth is often necrotic and is always soft and friable. The uterine wall may be infiltrated. Metastases in other organs are of similar character.

Histological Appearances.—In all cases that are to be regarded as syncytiomata the growth consists essentially of tissue identical with the syncytium and the cell layer of Langerhans. The relative proportion of these two varieties of tissue varies in different tumors and in different portions of the same tumor. In four cases from the collection of the Pathological Laboratory of the Massachusetts General Hospital the appearances agreed closely with Williams' descriptions and plates. The growth consisted of irregular masses of large cells, in every instance associated with syncytium. Both the syncytium and the cellular portion were identified by comparison with chorionic villi derived from an early pregnancy. The cellular masses are almost invariably surrounded by layers of syncytium, that is, the syncytium presents itself at the growing surface of the tumor. It is vacuolar over certain areas (see central portion of Fig. 4585). Some

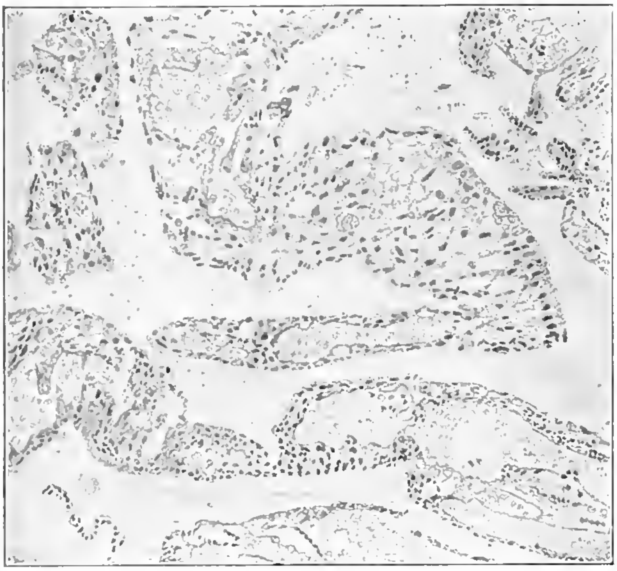

FIG. 4585.—A Section of Syncytioma which has Infiltrated the Uterine Wall. The tumor is made up of two sorts of tissues, a portion consisting of syncytium (to the right of the central portion of the figure), the remainder of separate cells corresponding to the cellular layer of Langerhans. There is no stroma in the structure of the tumor.

cells of the cellular portion attain a large size. Mitoses are numerous and atypical multipolar mitoses are not uncommon. There is no stroma and no blood-vessels are present, although blood is found free between the tumor cells. Large portions of the growth are necrotic, and a fibrinoid change is present, similar to that occurring normally in the placenta. In one case the growth is composed of villus-like masses. No mesenchyma and no decidual cells were found in these cases. The uterine muscle was infiltrated in each case. Metastases present the same histological appearances.

Theoretical Considerations.—As in other tumors, it is impossible here to arrive at an explanation of the causal agency of deciduoma malignum. It is not possible to ascertain whether the fœtal tissues for some unknown cause take on abnormal activity or whether the maternal structures are unable to resist the normal growth of this tissue. When, however, it is considered that these growths in all recorded cases follow pregnancy, that they arise at the placental site, and that they are composed of tissue derived from the fœtal ectoderm, their origin is clear. Whether there exist tumors agreeing clinically with these, but consisting of both fœtal and maternal tissues or consisting wholly of maternal tissue, as Sänger claimed, is a matter of dispute. Assuming, for the time being, their existence, they are not to be considered under syncytiomata.

MALIGNANCY AND METASTASIS.—The malignancy of deciduoma is striking, symptoms usually appearing during labor or within four weeks of that time. In a large percentage of the cases death occurs within six months after the appearance of the first symptoms. As a rule, metastases are abundant. In Dorland's series of 52 cases, metastases occurred in the lungs in 78.37 per cent., in the vagina in 51 per cent., in the kidneys, spleen, and ovaries in 13.5 per cent., in the pelvis and in the broad ligament in 10.8 per cent. respectively, and in the brain in 5.4 per cent. In a small number of cases the vaginal metastases have occurred where no primary growth could be found.

Clinical History.—The first symptoms noted are repeated and profuse uterine hemorrhages, while in the later stages there may be foul watery discharges. There is usually pelvic pain. Metastases may appear in the vagina with vulval œdema. The patient becomes cachectic, there is anæmia, and hæmoptysis may take place from pulmonary metastasis. Slight fever and occasional rigors arise from the absorption of septic material.

Diagnosis.—The possibility of deciduoma malignum should always be borne in mind after the expulsion of a hydatidiform mole or upon the appearance of profuse hemorrhage or obscure symptoms following delivery. In such instances curettage should be resorted to and the diagnosis made from the uterine scrapings. Vaginal metastases may be the first indication of the growth. Microscopical diagnosis is made by the appearance of syncytium in the growth.

Treatment.—If microscopical examination of the curettings reveals the presence of deciduoma, immediate hysterectomy should be performed and the metastases excised wherever they are accessible. The chances for ultimate recovery are, however, slight, so great is the rapidity of metastasis-formation.

Neumann claims to have obtained early evidence of the appearance of deciduoma through the examination of hydatidiform moles. He found among the cases which he examined certain moles in which the syncytium invaded the villi in a manner very suggestive of malignancy. The most marked of these cases afterward developed deciduoma. From his results it would seem justifiable to curette the uterus following the expulsion of a hydatidiform mole, in order to examine the scrapings histologically for the presence of deciduoma and for the purpose of removing the same. Hysterectomy is not justifiable on the evidence of a vaginal tumor, but should be performed only after a positive diagnosis from the curettings, for in certain instances the vaginal tumor exists without uterine involvement and its removal has been followed by complete recovery.

Ernest Edward Tyzzer.

SYNOVITIS, ACUTE.—(Synonyms: Hydrops articulorum acutus, Acute serous synovitis, Arthro-meningitis, Sero-synovitis; French, Synovite aiguë; German, Die Synovitis.)

ANATOMY.—Synovial membranes approach so closely to the serous membranes that they are often classified with them. But, although structurally much the same, they differ from the serous membranes in secreting a peculiar fluid, synovia. In all joints where motion takes place (diarthrodia) a lubricating fluid is necessary, and this fluid is furnished by the so-called synovial membrane. Every diarthrodial joint is lined with a layer of synovial membrane, except in the places where the articular cartilages are in contact. Here there is no membrane, except at the edge of the cartilages, which the synovial membrane may overlap for 2 or 3 mm. before merging into the cartilaginous structure. Fasciculi and folds of the capsule, the internal ligaments, and fatty internal protrusions are all covered by the membrane. The limits of the synovial membrane are most easily made out in inflammation, when a red collarette is seen surrounding the white cartilages.

Synovial membrane is thin and elastic. Externally it merges into the tissue of the joint capsule, while its inner surface is smooth and moist. Histologically the structure is a basement tissue of elastic and connective-tissue fibres, upon the inner surface of which lie endothelial cells. In gross, the inner surface of a joint presents a smooth and shining surface, interrupted, especially where the membrane folds to pass from one surface to another, by the synovial fringes (plicæ synoviales)—villous structures of varying size and length, somewhat resembling intestinal villi, the largest being perhaps 1 cm. long. They are richly supplied with blood-vessels, for each villus contains the convoluted twig of an artery. Some of the fringes, however, are merely hernia-like protrusions into the joint of small masses of fat covered by synovial membrane; these fill up unoccupied spaces. The nerves are derived from the same nerve trunks that supply the muscles of the limb. The nerve filaments terminate in small plexuses, unequally distributed, under the synovial membrane. Coloring matter injected into the joint disappears very quickly, to reappear in the lymphatic channels of the limb.

Synovia is a clear, alkaline fluid, much like the white of egg in general appearance; when rubbed between the fingers it imparts an oily sensation. It is largely secreted by the cells which cover the synovial fringes. In composition it contains albumin, mucin, some fat, leucocytes, and epithelial cells. A fluid identical in composition with synovia can be produced by rubbing up a portion of the epidermis in a weak alkaline solution. This fact suggests that most of the mucin is derived from the endothelial cells soaking in the weak alkaline fluid secreted by the fringes, and this view is strengthened by the fact that, when joints are quiet, the synovia in them contains only half as much mucin as when they are in motion.[1]

PATHOLOGY.—The classification of acute inflammations of the synovial membranes is best made according to the character of the effusion: (1) Serous; (2) serofibrinous; (3) purulent.

(1) Acute serous synovitis is the most common of all. The pathological process is simple; for some known or unknown cause a joint, most frequently the knee, becomes the seat of an inflammation which is manifested in the usual way. There are hyperæmia of the vessels of the membrane, an increased rapidity of the blood current, and then dilatation of the capillaries, with stasis. Migration of the white corpuscles from the vessels follows, and a profuse serous secretion is poured out from the dilated vessels into the perisynovial tissues and into the joint. The endothelial cells are very rapidly produced, and are cast off, half formed, into the joint. This process, carried far enough, constitutes "catarrhal synovitis," a purulent form. To the naked eye the surface of the membrane is seen to be bright red, from the dilatation of the surface capillaries; it is not so shiny as usual, and has ordinarily a boggy, softened, œdematous appearance, from infiltration, which is most noticeable in the synovial fringes. Here and there, especially in the more acute cases, may be seen a patch of extravasation, where a distended blood-vessel has burst. The fluid in the joint is often colored more or less red by these extravasations. The cartilages in an inflammation of this grade are not affected, but are seen to be of a clear bluish white color, and surrounded by the sharply marked line of inflamed synovial membrane.

The joint at this stage is more or less distended with an abnormally large amount of synovial fluid, at first thinner than usual, on account of the copious effusion of serum into the joint, then becoming more or less opalescent as the endothelial cells are cast off into it and become macerated, and as the leucocytes increase in number. The amount of fibrin in the fluid varies greatly; in severe acute attacks the amount is generally so large that the fluid is glairy and sticky, and, on standing, distinct flocculi separate out and float around. When there is so much fibrin in the joint fluid that it consolidates on the synovial surfaces, the case belongs rather to the class of serofibrinous effusions. At this stage, unless it become chronic, the inflammation subsides or goes on to the formation of a purulent exudation. If it subsides, the blood supply diminishes, the newly formed capillaries are obliterated, the distended ones resume their normal calibre, the cell proliferation ceases, the cells already thrown off furnish mucin to the synovia, the excess of fluid is absorbed, and everything returns to a normal condition. The synovitis is cured.

(2) Acute synovitis of the serofibrinous type may be manifested more in the synovial tissue than as an effusion. In such cases the swelling is more dense than fluctuating. Thickening of the capsule may be prominent. The joint is filled with a yellowish fluid, and the synovial membrane is bluish-red in color and the surface is smooth but irregular. Adhesions between opposing surfaces occur very early. Microscopically, more leucocytes are found in the tissues than in the serous form, and extravasations of blood are frequent in the capsule. A layer of fibrin adherent in places is to be found, and in parts the joint surfaces seem to have degenerated into fibrinoid tissue. The likelihood of the growing together by adhesions of parts of the joint which are in contact must again be mentioned as the most striking and most dangerous characteristic of the affection.

(3) Synovitis with purulent effusion (empyema articuli; katarrhale Gelenkeiterung, von Volkmann) may be a continuance of the serous form or may originate *de novo*. In the catarrhal or more superficial form[2] the pus is secreted by the surface layers of the synovial membrane and no deep-seated lesion necessarily results. In a severer grade, spoken of sometimes as suppurative synovitis, in contradistinction to the term purulent synovitis as applied to the catarrhal form, the deeper layers of the joint membrane are involved. In synovitis with purulent effusion cell proliferation and the migration of leucocytes become a prominent part of the process; and besides, where there was formerly serum there is now a seropurulent or purulent fluid. The synovial surface becomes velvety in appearance, and the cartilages become yellowish-white and their surface is indistinct and covered with lymph and flocculi of pus. Pyogenic cocci are present. In some cases the destructive process seems localized, and ulcerations of synovial tissue, and even of cartilage, take place, while the surrounding parts show only a moderate grade of inflammation. From this it is easy to see how any amount of mischief may result. The whole synovial membrane may become granulating tissue, the cartilage is perhaps eroded also, the bone is bare, and the periarticular tissues become the seat of abscesses as soon as the capsule breaks, perhaps before. It is hard to set a limit to so destructive a process as this.

Recovery from purulent synovitis may be complete, and no trace of the mischief may be left behind. Generally, however, recovery from suppurative synovitis means a joint impaired by adhesions. On the other hand, as we have seen, there is no limit to the destructive possibilities of suppurative synovitis; complete disorganization of the joint, dislocation of the bones, and, worst of all, systemic infection are only too apt to follow.

SYMPTOMS.—In few pathological conditions are the four classical symptoms of inflammation more marked than in acute synovitis. Pain, heat, redness, and swelling comprise a large part of all that can be said of it.

Pain.—In simple acute synovitis, a few hours after the receipt of a wound or blow, some wrench, some exposure, or overexertion of a joint, commonly the knee, an uneasy, hot feeling is noticed, and before long it becomes a positive pain. This is associated with a tense, burning feeling and a sense of helplessness in the affected limb. Any motion adds to the discomfort, and manipulation of the joint, if carried to extreme flexion or extension, causes pain; sometimes any motion at all is painful. The feeling of distention that accompanies the height of the effusion may be distressing, but from the sixth, seventh, or eighth day, when this height is reached, the pain rapidly subsides. The pain is ordinarily felt in the joint that is inflamed, but it may be "reflected" to some other joint supplied by the same nerve trunks. This curious phenomenon is most frequently noticed in hip-joint inflammation, in which disease the pain may be referred to the knee of the affected side. The intimate relations and anastomoses of the sciatic, obturator, and anterior crural nerves seem to furnish the best explanation of this. When the synovitis becomes purulent, or is so from the first, pain is a more prominent symptom and much more severe than it is in simple synovitis. The pain is severe in serofibrinous synovitis; these are the cases of joint disease in which pain, and not swelling, is the prominent symptom, in which no pus can be found, and in which ankylosis is most rapid and unexpected. If it goes on to destruction of the joint structures and to ostitis, the pain becomes extreme, and the patient is waked from sleep at night by the muscular jerks (starting pains), which press the inflamed and ulcerated joint surfaces together. Even in simple synovitis the pain is worse at night.

Tenderness.—Along with the pain goes tenderness in most cases, as one would expect from the inflamed condition of the synovial sac and the irritable state of the articular nerves. In purulent synovitis the tenderness is generally greater than in the serous variety. The ordinary tenderness is the pain felt on deep pressure and manipulation of the inflamed joint. There is a spot in each joint where tenderness is apt to be especially marked. In the knee it is over the inner condyle, about a finger's breadth inside of the inner border of the patella; in the ankle-joint, in front of the outer malleolus; in the hip, in front of the great trochanter. The pain meantime is by no means localized, but there is a bruised, helpless feeling extending to the whole joint. Certain cases, however, are characterized by severe local pain and tenderness in some one spot.

Swelling.—In simple serous synovitis intra-articular swelling begins on the first, second, third, or fourth day. It is of two kinds—effusion into the joint and effusion around the joint. In simple synovitis the infiltration into the periarticular tissues is slight, but if pus appears the skin becomes red and boggy. The same is true of the synovitis associated with acute rheumatism, where the peri-articular infiltration makes a shapeless and puffy joint; whereas intra-articular distention betrays itself by a characteristic shape in each superficial joint, dependent upon the elasticity of each synovial sac. This intra-articular distention varies from a small effusion up to a condition in which the skin is shiny, tense, and pale, and the venous return from the lower segment of the limb may be impeded. The capacity of the sac of the knee joint, when extremely distended, is some six or seven ounces, in average cases of simple synovitis it holds about four ounces. The average capacity of the shoulder-joint sac is three ounces. But in the deeper joints swelling may not be so readily discoverable. The common state of affairs in both hip- and shoulder-joints acutely inflamed is a general enlargement of the joint, without the clearly articular shape which is to be seen, for instance, in the knee and elbow.

Redness and Heat.—Redness is not regularly present in simple synovitis. The pyæmic and the gouty or rheumatic forms of synovitis are apt to be attended by a blush, which is generally quite marked in the two latter affections. In the case of the deeper joints redness as well as heat is ordinarily absent. In superficial joints more or less local heat about the inflamed joint is present. If the synovitis is purulent, the local rise of heat is as great as in any acute purulent inflammation.

Position.—When in a state of acute inflammation a fairly constant abnormal position is assumed by each joint; the semiflexion of the knee in knee-joint synovitis will serve well enough as a type. The hip is flexed and adducted or abducted, the ankle is slightly extended, the arm is carried at the side, the elbow is flexed at about a right angle, and the wrist drops slightly and is somewhat flexed. Fixation of the muscles holding the joint is present at the same time, and the abnormal position is firmly maintained by them when manipulation of the joint is attempted. At first this muscular guard seems to be purely voluntary, and is only excited by the pain which movement causes, but in time it becomes involuntary, until in chronic joint disease it may be present in cases in which movement causes no pain at all. This is apparently due to the fact that in that position the joint is more comfortable than in any other.[3,4,5,6,7]

Muscular Atrophy.—Atrophy of the muscles controlling an inflamed joint begins early and may be very marked, even in a simple acute synovitis. The character of the joint disease seems to matter but little in the production of this phenomenon. Traumatic or simple, acute or chronic, serous or purulent synovitis, all show muscular atrophy, and the more acute the disease, the faster the wasting goes on. That this is something more than the mere atrophy of disuse is shown by the facts that it begins so sharply and so early, that it is greater in the diseased limb than in the well one, even when the patient has been in bed from the first, and that the muscles, although atrophied, are not soft and flabby, but tense. Valtat[8] injected the joints of guinea-pigs and dogs with irritant solutions, mustard-oil and ammonia, and found that muscular atrophy came on quickly. In one case, in eight days there had been a loss of thirty-two per cent. by weight in the anterior thigh muscles, and twenty-four per cent. in the anterior calf muscles; in another case it reached forty-four per cent., and in all cases the extensors wasted more rapidly than the flexors. He attributes much influence in the matter to the amount of pain present.

Paralysis.—Valtat also calls attention, in this connection, to the paralysis of the muscles of the affected limb often accompanying acute joint disease, the loss of power already mentioned, and also a diminution of faradic excitability after severe muscular wasting. Such a paralysis, to a greater or less degree, seems to precede the wasting of the muscles.

General Condition.—The general condition of a patient with simple acute synovitis suffers but little. The rise of temperature, if any, is slight, unless a rheumatic condition exists, and only with the advent of pus does the temperature rise to any extent. A sudden chill, an increase of pain, a tendency to fever, all make one suspect the formation of pus, and when that has once come the general condition may become really serious. Gonorrhœal, rheumatic, and pyæmic synovitis are accompanied by fever and the other symptoms of the affections which they represent.

VARIETIES.—Considered in relation to cause, acute synovitis may be divided into two classes, traumatic and non-traumatic.

Traumatic synovitis results from a sprain, a blow, or a wrench to a joint, or from an intra-articular fracture, and is characterized as a simple serous synovitis. Often a simple synovitis may arise without an obvious trauma, and such cases may be classed as traumatic, assuming that they arise from overuse or some similar cause; but such cases are more usually, without sufficient evidence, classed as rheumatic. It would seem better to restrict the use of the latter term to those cases which occur in connection with other rheumatic manifestations.

Traumatic purulent synovitis is likely to result from penetrating wounds of the joints, where micro-organisms are introduced by the penetrating instrument. In a day or so after the infliction of the wound swelling, pain, and malposition come on, and the joint is found to be distended with a seropurulent or purulent effusion.

Among traumatic causes must be mentioned a very important class of cases in which some mechanical imperfection of the joint is the cause of the attack. This is especially to be observed in the knee. A semilunar cartilage may be torn loose and cause one or a series of attacks. An hypertrophied synovial fringe may be present and by being caught in the joint may cause an effusion. Or a foreign body may act as an irritant cause.

The most frequent of the non-traumatic forms of acute synovitis is the rheumatic, classed by Schuchardt as a hæmatogenous infection. *Rheumatic synovitis* is in the lighter cases serous or serofibrinous, while in the severer ones it is fibrinous. Purulent synovitis is very rarely observed. It is generally polyarticular and the swelling involves the parts about the joint as well as the synovial membrane. Even the apparently monarticular form is apt to be preceded by pain in other joints. It shows a strong tendency to become subacute or chronic, and in the severer grades is likely to result in a distinct loss of mobility.

Gonorrhœal synovitis, known as "gonorrhœal rheumatism," follows no definite type, being monarticular or periarticular.[9] It occurs in the later stages of the gonorrhœa and affects most often the knee, then the ankle, foot, wrist, etc., in the order named. The effusion if serous is thick. It may be seropurulent or purulent, and is at times colored with blood. In the severer cases the changes do not differ essentially from those which occur in pyæmia, the striking feature being the large amount of granulation tissue formed.

Impairment of motion and ankylosis are greatly to be feared. The affection is due apparently to the gonococcus. This may be found present in the joint effusion, it may be absent, a mixed infection with pyogenic organisms may exist, or pyogenic organisms may be present alone. The most notable feature of the affection is its obstinate and intractable character.

Synovitis in Acute Infectious Diseases.—Synovitis from hæmatogenous infection may occur in various other acute infectious diseases. The type of such inflammations is to be found in pyæmia.

The diseases in which synovitis thus develops are the following: Scarlet fever, measles, variola, varicella, typhoid fever, pneumonia, diphtheria, dysentery, cerebrospinal meningitis, pertussis, glanders, pyæmia and septicæmia. It is also occasionally encountered in other infectious diseases. The varieties may be the serous, the serofibrinous, or the purulent.

The cause is to be attributed to the organisms which give rise to the original disease, and one finds most often a mixed infection with pyogenic cocci; but the bacteriological findings are uncertain, the fluid may be sterile, it may contain the specific organisms of the original disease, or it may contain pyogenic organisms.[10]

The nature of such cases is most often serious, and joint destruction may be rapid and extensive in the purulent forms. General intoxication is likely to be present, and metastatic foci in other organs may coexist. Especial attention has been paid to the pneumococcus joint infection which occurs at times in pneumonia.[11]

Synovitis from Immediate Infection.—The form of synovitis resulting from penetrating wounds has been classed here as traumatic and mentioned above. Areas of infection in the neighborhood of the joint may, however, cause a joint inflammation, most often of purulent character. The most common form of this is to be found in acute infectious osteomyelitis existing in the ends of the long bones and reaching the joint. Such an infection results in an acute destructive purulent synovitis, an example of which is to be found in many if not most cases of the so-called "acute arthritis of infants." In these cases a very severe purulent joint affection appears in young babies,—an affection which is characterized by rapid and destructive progress and severe general infection.

Among other causes of infection by contiguity may be mentioned all the cases of synovitis which occur when phlegmon and abscesses develop near a joint or when erysipelas passes over it. Acute periostitis and acute and chronic ostitis occurring near a joint are other causes of joint infection.

Syphilitic Synovitis.—Simple serous synovitis may accompany the secondary stage of syphilis, The more characteristic syphilitic lesions are chronic. Acute synovitis is rare in hereditary syphilis.[12]

Synovitis in Hæmophilia[13] is rather a chronic than an acute affair; but acute swelling, pain, and disability occur in connection with trauma, and as an accompaniment of the chronic process existing in the joint. There may be extensive intra- or extra-articular hemorrhage in connection with this.

Intermittent synovitis, which is an affection characterized by a succession of acute attacks of synovitis (of the knee) is an affection the pathology and etiology of which are very imperfectly understood, and for which no satisfactory treatment has been formulated. Periodicity is a marked feature of the attacks.[14]

Gouty Synovitis.—Gouty synovitis is the local manifestation of the general disease. It is a serous synovitis, ordinarily of the great toe joint, with considerable periarticular infiltration and redness of the skin. It tends to involve other joints in succession. There is a chronic structural change in the joint, which is merely interrupted by these attacks of acute synovitis.

Similar acute attacks occur in other forms of chronic synovitis.

Catamenial Synovitis.—A synovitis is described as occurring in girls and women in connection with menstrual irregularity or uterine trouble. It is usually bilateral and painless.[15]

DIAGNOSIS.—The swelling produced by the distended capsule is the most characteristic sign; it is irregular in outline, bulging, and fluctuating, where the joint is superficial. In the ankle-joint the swelling is not very clearly marked, but it ordinarily is chiefly anterior and the capsule bulges out in front of the malleoli. In the knee the patella is lifted by the effusion and floats. In examining for this the knee should be fully extended and the muscles relaxed, the fingers of both hands should encircle the limb firmly in front, above, and below the patella, thus confining the effusion to the space directly under the patella and over the intercondyloid depression on the femur. The forefinger of one hand then lightly but sharply presses on the patella, which can be felt to descend and hit the femur. This matter of fully extending the leg and confining the effusion under the patella is of much importance, as otherwise a small effusion may escape detection. Acute synovitis of the hip is a rather obscure affection, and in children the diagnosis from beginning hip disease is not always possible. In cases with much effusion in adults, however, swelling may be found in the groin above Poupart's ligament and behind the great trochanter. In the hip there is generally limitation of motion and the leg may be flexed and abducted. In the case of the shoulder the whole joint is larger than usual, without any definite outline; and if the distention is great, the axilla may be more shallow than is normal, and the depression beneath the acromion behind is lost. In the elbow there is bulging of the sac behind on each side of the triceps tendon. The wrist, when inflamed, shows an encircling swelling. The positions assumed by the various joints, when inflamed, have been given above, but simple position is of little service in differentiating synovitis from other joint and bone affections, and the same is true of muscular atrophy.

It is important to remember not only that synovitis is made evident by effusion, but also by swelling of the synovial membrane, and in the more superficial joints the latter is easily detected. In the knee-joint, for instance, by palpating the parts at the sides of the patella where the synovial membrane lies over the bone, much information may be obtained by contrasting the affected with the sound joint. The inflamed membrane feels thick and masks the clear outline of the bone.

Synovitis is to be distinguished from ostitis, bursitis, articular neuralgia, and hysterical joint disease. A diagnosis of acute synovitis in children should be made with very great care, for they are not prone to have acute synovitis, and are prone to have chronic ostitis. Typical bone disease begins with stiffness of the joint and pain—the latter especially at night, interrupting sleep; wasting of the muscles of the limb, and effusion are not necessarily present. There is generally some constitutional disturbance and the course is slow.

In children, however, the bone disease may have escaped attention and a supposed fall may be the first thing to call attention to the fact that a child limps. A very considerable number of cases of hip disease, for example, come to out-patient clinics with a history of the trouble having dated from a fall a few days previously, when it is obvious that the disease must have existed for weeks at least.

From bursitis, synovitis is distinguished by the different location of the swelling, the less degree of joint stiffness and pain, except when manipulation bears directly on the inflamed bursa, and the absence of muscular atrophy. In the case of deep bursæ the differential diagnosis may not be easy at first. Bursitis, however, rarely begins without cause; it is associated oftenest with mechanical irritation, as the names "housemaid's knee," "miner's elbow," etc., show. At the same time it should be remembered that bursæ often communicate with joints, and that synovitis and bursitis may exist together during an acute synovial inflammation. The bursæ, when inflamed, form in their way as characteristic a swelling in each joint as does the joint capsule itself when distended by intra-articular effusion.

Articular neuralgia is said to exist apart from joint disease.[16] Local symptoms are absent and the condition is too vague and too little known to deserve more than mention.

Hysteria simulates chronic oftener than acute joint disease, yet sometimes, following a fall or an overexertion, sensations closely simulating the symptoms of an acute synovitis may be complained of. Ordinarily the diagnosis is easily enough made by the absence of heat, swelling, and localized tenderness, and by the general make-up of the patient, but some cases offer much difficulty, as muscular wasting and rigidity may be present.

Pyæmic, gouty, and rheumatic synovitis are to be distinguished from each other by the presence of the constitutional affections of which they are merely the symptoms, while gonorrheal synovitis often offers some little trouble from the fact that the patient is anxious to conceal his urethral discharge. Rheumatoid arthritis belongs rather to the class of chronic joint diseases, and would hardly be confounded with acute synovitis.

As to the diagnosis of dry synovitis, few rules can be formulated. Its acuteness, severe pain, and the absence of marked swelling are its leading characteristics. To diagnosticate it from ostitis would be sometimes impossible, but ordinarily its more acute course will establish its identity. At best it must remain an obscure affection.

Prognosis.—The prognosis in simple serous synovitis of traumatic origin in adults is good, if the general condition of the individual affected be even fair. Suppuration is not common, except from wounds; and when it occurs, there is generally some evident cause for it, such as infection by tapping, a broken-down constitution, etc. Under effective treatment a complete restoration of the joint is the rule. From the sixth to the eighth day the effusion will ordinarily begin to subside, and its absorption is much aided by pressure and rest. The third possibility, in a simple synovitis, is that it may become chronic. In some cases the swelling does not subside much, but the pain goes away, and, although the joint remains swollen, the patient may go to business and use the leg to a moderate extent; but he has dropsy of the joint, chronic serous synovitis, or an irritability may remain after the absorption of the fluid, and succeeding light attacks may follow one another, each leaving the joint worse than it was before. Cases like this are apt to eventuate in chronic joint disease.

In acute synovitis which is caused by displaced cartilages, by hypertrophied fringes, or by foreign bodies, the disease is likely to recur. Rheumatic synovitis, on the other hand, has a tendency to become subacute or chronic and to leave stiff joints. The occurrence of suppuration in either rheumatic or simple synovitis is a serious matter, and, although prompt treatment will, in most cases, be efficient, a much more doubtful prognosis will have to be given, especially if the suppuration should have come on without apparent cause. The prognosis must depend on the treatment, and the prompt making of a free incision improves the outlook greatly. However, in purulent synovitis of any severity some impairment of motion is to be feared. The occurrence of a joint affection in pyæmia does not make very much difference in the outlook, for the prognosis depends wholly upon the general character of the disease, whether mild or malignant. If it is mild, in from five to ten days the joint symptoms improve, and a complete restoration of the joint is not impossible.[17] On the other hand, the destruction may go on to any extent, preceding a fatal termination. In general, however, it is not common to find complete restoration of joint function after purulent synovitis, although it may take place. The synovitis which occurs after the exanthemata is said to tend toward recovery after a few days. At the same time, bearing in mind how often chronic joint disease follows these exanthemata,[18] the physician should be careful not to give an unreservedly favorable prognosis. The synovitis which develops in typhoid fever is generally purulent and more grave. Gouty synovitis, when left alone, lasts for a week or ten days; efficient treatment will generally shorten its course to three or four days. Gonorrhœal synovitis is at best a slow affair; it is characterized by a slow course, with a tendency to relapse and to become chronic. Recovery does not ordinarily take place in a less time than a month or six weeks, and ankylosis is common.

The occurrence of synovitis as a complication in chronic ostitis is merely an incident in the course of a long disease.

Treatment.—The most important points in the treatment are: to put the joint at rest and to keep it at rest; and, secondly, in the severe cases, to put the joint at rest in good position, so that if ankylosis should take place, as useful a limb as possible may be obtained. The knee, for example, should be put up very slightly flexed, the elbow at a right angle, with the thumb upward, the hip very slightly flexed on the trunk and neither adducted nor abducted, the ankle at a right angle, the wrist in the line of the arm, and the shoulder with the arm at the side. The splint that offers the most definite and absolute support to the two segments of the limb is to be chosen. Ordinary wooden and tin splints, accurately padded and firmly applied, are generally the most serviceable, except in the ankle, where in severe cases carved wooden side-splints often will not answer, and wet millboard or plaster of Paris must be applied; and in the hip, where bed-extension and a long outside splint, as in fractured thigh, will be most serviceable. Millboard splints are applied according to the directions of Gamgee.[19] The joint is wound by rollers of sheet-wadding until one or two layers cover it everywhere; then wet millboard is shaped to the joint and bandaged on by cotton rollers, applied with firm, even compression, which may be considerable if the method is properly applied. Plaster-of-Paris splints are made by the application of crinoline-gauze bandages impregnated with finely divided plaster. The limb is first wound in sheet-wadding or gauze, and then the plaster rollers are applied. The method does not give in all cases certain, definite support.

The problem of getting a limb into good position for the application of a splint is not always an easy one. The knee, for example, is apt to be more flexed than is desirable, especially in a case of some days' duration; and, if easy manipulation fails to bring it into correct position, recourse must be had to manipulation under ether, or to extension by weight and pulley, before a ham-splint can be applied. The former of the two methods should be chosen in most cases of acute synovitis. Once obtained, this good position is easily kept. It is not generally practicable to apply extension to the wrist or the ankle. The plan of putting up the limb in whatever position it happens to be, and waiting for it to straighten under rest, is not always effectual. With the larger joints rest in bed should be enforced for a day or two in cases of severe sprain.

After the limb has once been placed in a good position, and after precautions have been taken for maintaining it in this position, it will not be necessary, in a case of simple synovitis of moderate severity, to do very much more. The distended sac may advantageously be subjected to a moderate degree of compression. This may be effected in a variety of ways. A flannel bandage affords light compression; small dried sponges, laid over the joint and held in place by stout linen rollers, and then wet, afford either the lightest or the most severe compression. The application of a rubber bandage is one of the most common forms of producing compression. It can be loosely applied so as to produce but light pressure, or, by stretching it only slightly during its application, very severe compression may be obtained. The method of Gamgee, above alluded to,[19] is applicable to almost any joint, and affords even, comfortable, and efficient compression. If, however, the intra-articular distention is extreme, or if at the end of a week it does not begin to diminish, the joint should be aspirated and compression at once applied.

The application of cold to the joint often gives relief to the pain and a sense of comfort. This can be done by a poultice of ice and sawdust, by the ice-bag, or by the rubber coil wound around the limb. In other cases hot applications are more agreeable and equally useful. Hot-water bags can be used, or poultices, or fomentations of laudanum and hot water. In synovitis of a severe character in a full-blooded individual the application of leeches to the joint might be of value. Painting with iodine, blistering, firing, and the other forms of counter-irritation seem a needless and bothersome infliction in simple acute synovitis; if, however, it shows a tendency to become chronic, then the time for counter-irritation has come, and blisters encircling the joint, in connection with aspiration and subsequent compression, should be made use of. When the effusion has subsided and only a moderate thickening of the tissues is left, the splint should be removed for a little while at a time and passive motion begun, along with massage. The tendency which inflamed joints have to become ankylosed should always be borne in mind. If the splint is kept on too long, muscular atrophy is increased and the subsequent weakness of the limb may continue a long time and be a source of discomfort and of irritation of the joint. If the patient be permitted to use the joint too soon, there may be a recurrence of the effusion and other acute symptoms. In the knee, for instance, free use should not be allowed until the effusion has wholly disappeared and the thickening of the synovial membrane about the joint has greatly diminished.

Massage is indicated as soon as the heat and extreme tenderness of the early stage have disappeared. As to methods of manipulation and massage, a skilled masseur is, of course, the best person to handle the limb, but deep kneading of the muscles and gentle flexion and extension of the joint, increasing in extent each day, are better than nothing. The muscular atrophy will cause the limb to be weak; and, if the atrophy has reached an advanced degree, although the muscular tone would probably in the course of time be restored without such help, the restoration can be hastened by the use of a weak continuous current, or, if preferred, the faradic current may be employed. The use of hot-air baths is of great value in the later stages of acute synovitis.

It is not worth while to attempt to use the limb very much until its function is fairly well restored by passive motion. The use of oil, etc., is, of course, much inferior to massage with the dry hand, but if the pain persists, on using the limb, stimulating liniments and iodine are useful.

If ankylosis should have already taken place, there are two methods to pursue: (1) To break it up at once under ether, a method which will ordinarily cause a relapse of the synovitis; or (2) to wait some months before attacking it. The latter method will generally be advisable.

Slight grades of acute serous synovitis of traumatic origin are best treated by massage from the first. The massage should be given by some one of skill and experience and not oftener than twice daily. The patient may be permitted to use the joint provided it be properly protected. In the ankle, for instance, a pad of felt under the arch of the foot, held in place by a firm bandage or strips of sticking plaster running under the foot and winding around the ankle (Cottrell's dressing), will enable the foot to be used without pain, whereas its unprotected use would be harmful and accompanied by much pain.

The application of dry heat in a hot-air oven is also of much value in these cases. The joint loosely wrapped in flannel is exposed to a temperature of 300–400° F. for half an hour or more once daily. This treatment may often be profitably combined with massage, one treatment of each being given daily.

The constitutional treatment of acute serous synovitis amounts to nothing more than the routine of keeping the bowels open and administering diaphoretics if the temperature is elevated. If, however, there is any reason to suspect a rheumatic cause for the attack, salicylate of sodium should be given in full doses.

Traumatic purulent synovitis, where a penetrating wound of the joint exists, requires the enlargement of the penetrating wound and the free flushing out of the joint with hot sterile water or with weak antiseptic solutions. The wound may then be closed if the case is recent. If the case is not recent and if the infection of the joint is well established, free incisions should be followed by prolonged flushing out of the joint with a weak corrosive solution used hot, and the wounds should be drained.

Rheumatic synovitis should be treated by rest, compression, and ice-bags, along with the appropriate use of salicylic-acid compounds for the general condition.

Gonorrhœal synovitis should be treated in the acute stage by rest and compression. As soon as this passes, the use of hot air and massage will be found of value. Should the case prove intractable, much improvement may often be secured by opening the joint, flushing it out freely with hot water, and closing it again.

Synovitis in acute infectious disease, so long as it remains serous, is treated like any severe case of serous synovitis. So soon as it becomes purulent the joint should be opened freely and washed out and the wound closed or not, according to circumstances.

In *synovitis from infection from contiguous parts*, the opening of the joint is indicated, and at the same time the cause of the infection should be removed, if possible.

Syphilitic synovitis is treated on the general lines indicated, and antisyphilitic treatment should, of course, be given.

Synovitis in hæmophilia is treated by rest, cold, and compression.

Gouty synovitis is treated by rest and constitutional measures.

SYNTHETIC PRODUCTS, POISONING BY.—Out of the large number of synthetics obtained from the hydrocarbons of coal-tar a few have come into general medical use, and one of these, acetanilid, is a common ingredient of the headache cures sold by druggists. Antipyrin and phenacetin are also much used, but, being more expensive, are less common in proprietary articles. All these bodies are antipyretics, and when taken in overdose, produce depression of the heart, with slow respiration and lowered temperature. Marked cyanosis is also observed. Nausea and vomiting may occur. The effects of the drugs are much influenced by idiosyncrasy. The treatment should be free washing out of the stomach, artificial warmth to counteract the antipyretic action, and stimulants, alcohol and coffee, to counteract collapse. Inhalations of oxygen have been suggested; also the hypodermic use of strychnine.

Sulfonal, trional, and tetronal are members of a group of synthetics that have hypnotic action, and have been used as substitutes for morphine. Sulfonal has been much used. These agents may cause vomiting and purging, but not usually. In fact, the bowels are often constipated. Sometimes the most marked symptom is depression, but the typical effect is sleepiness which deepens into coma, and may last for a long while. The urine is diminished and becomes very dark, owing to excess of a coloring matter. This symptom, known as hæmatoporphyrinuria, is generally early developed. In a case of trional poisoning recently reported, the patient, a woman aged twenty-eight, had well-marked hallucinations with dizziness, staggering, and loss of reflexes. The change in the urine came on late. The patient was in bad health when she took the drug. She died from the effects.

Treatment of this class will be carried on along somewhat the same lines as those given above. The stomach should be washed out well. As the drugs are eliminated by the kidneys in unchanged form when the dose is large, it is deemed advisable to use warm water freely as a diuretic. Constipation will be, of course, met by mild purgatives or enemata. *Henry Leffmann.*

SYPHILIS.—The word syphilis was probably first suggested by *Syphilus*, the name of one of the characters in a pastoral poem composed by Fracastor in 1530. This name was unquestionably coined by the poet for his fictitious character, by a combination of σῦς, hog, and φίλος, fond of—a not uncomplimentary designation for swine herd.

Definition.—Syphilis is a specific, infectious, and chronic disorder, resulting either from inheritance or from immediate or mediate transference of the disease from an infected to a sound individual, beginning always, in the latter event, after the lapse of a characteristic incubative period, by the appearance of an initial lesion, at the site of infection, commonly termed a chancre; and followed after an interval of time by symptoms of systemic derangement, often evolved in a determinate order, which eventually may affect any organ of the body, one attack usually conferring upon the subject of the disease immunity against subsequent infection.

Synonyms.—Many of the names which have been employed to designate the disease seem to have originated in attempts to shift the reproach of its origin and existence from the people of one nation to those of another. It has been called morbus gallicus, the French disease, lues venerea, mal vénérien, vérole (in France), sifilide (in Italy), French pox, chronic pox, "bad disorder," "bad disease," Lustseuche, Krankheit der Franzosen, radezyge (in Sweden), and other names. The discovery of the micro-organisms responsible for the production of frambœsia and yaws has differentiated completely the three affections.

History.—Toward the close of the fifteenth century—soon after, in fact, the discovery of a new continent—syphilis made its appearance among Europeans and became the subject of discussion in medical literature. By many it was then supposed to have originated in consequence of the relations newly established between the inhabitants of the Old and those of the New World, and it was therefore often termed the "American disease." Later investigation, however, makes it appear possible that syphilis appeared among the races of men at a more remote period of antiquity. Evidence of supposed syphilitic disease of the bones has been recognized in the skeletons of prehistoric man.

Interest has been revived in the questions relating to the supposed American origin of syphilis by fresh studies of original documents, and by discoveries, in different portions of the continent, of bones supposed to exhibit changes due to the disease. Papers touching on the theme originally well elucidated by Joseph Jones, of New Orleans, have appeared from the pen of Bruehl and others, throwing further light upon both sides of the problem. The writings of Sahagun, Torquemada, Roman, Mendieta, Pane, and others have been found to show, as to New Spain, that the bodies of those affected with syphilis were interred, as distinguished from those dead of other disorders, which were cremated; that the infected were not deemed fit for religious sacrifices; that they were not represented at the festivals; and that the disease was counted a punishment sent from the gods for the non-performance of religious rites and for other offences. The Mexicans not only recognized the connection between the earliest and later manifestations of the disorder, but distinguished between several types of the former, understanding also its remedial treatment far better than the Spaniards, and even seeking thermal resorts for the purpose of securing relief. In seventeen Indian dialects, each of which has a primitive and native term for designating the disease, none of the terms thus employed suggests confrontation with a new malady, although soon after contact with the whites the natives were compelled to apply new names to many novel objects with which they were to become familiar. These new names either bear witness to the impression on their ears made by the speech of the Castilians, or describe some prominent feature of the object to be newly named, a rule distinctly observed by them in the case of diseases known to have been imported from Europe to America, as, for example, measles and smallpox. The singular confusion, existing in the Mexican language of the sixteenth century respecting the terms employed to indicate ideas of power, divinity, and the special disease here under discussion, possesses an interest in view of the fact that this is recognized in the dialects of Quechua and Aymeras, three hundred years before Pizarro conquered the capital of the Incas.

Symptoms scarcely to be distinguished in their description from those of syphilis are described in the ancient literatures of China, Mexico, Peru, Arabia, Greece, Rome, and in the sacred writings of the Hebrews. It is probable that, at the periods which have been assigned for the origin of the disease in the fifteenth century, its rapid extension was largely due to the awakened activities of mankind in the direction of geographical discovery and international traffic. It is a well-known fact that epidemics of infectious diseases are usually most severe in communities which have long been virgin of such accidents.

The literature of syphilis may almost be said to date from the period so long assigned as that of its first appearance among the races of men. It has since been adorned by the names of such eminent medical authors as Astruc, Van Swieten, Boerhaave, Bell, Sydenham, Colles, Hunter, Ricord, Gross, and Bumstead. The contributions to the subject made by contemporary authors have been as voluminous as valuable. The evolution and involution of the syphilitic process in every organ and tissue of the body have been observed and described with as much detail and accuracy as have been bestowed upon any of the problems in medicine.

Geographical Distribution.—Syphilis exists to-day in almost every country to which commerce has pushed its ventures. The degree of its depredations in any province may be wellnigh regarded as a measure of the extent of the intercourse of the inhabitants of such a country with the world at large. It exists in Great Britain, Russia, France, Italy, Norway, Sweden, Denmark, Prussia, Austria, Portugal, Switzerland, and in every other country of Europe. Its victims are usually more numerous in the larger centres of population where the activities of trade are greatest. England, for example, with her enormous maritime traffic, pays a heavier price of this character for her commercial profits than France, which is popularly supposed to suffer in larger measure. In a few of these countries, Italy, for example, where many of the people are densely ignorant, filthy, and poor, epidemics of the disease have occurred with disastrous results. On the African coasts, in Egypt, Madagascar, and Abyssinia; in all countries of Asia with which Europeans sustain commercial relations; in Japan, where the disease is reported to be both widely prevalent and virulent; in the Levant; in all parts of Asia Minor, and throughout all districts lying upon the shores of the Black Sea, syphilis is found, varying both in types of intensity and in preponderance. The same is true of all the countries of North and South America, Oceanica, and the Hawaiian Islands. In the United States of America, syphilis may be recognized in every hospital and in the practice of almost every physician of repute. It is fortunately, however, much more common in the large cities, the rural populations escaping to a happy extent. It is found here among those who are native to the soil, including the negroes and Indians, as well as among the Chinese and other individuals of foreign birth who have immigrated hither.

It appears, in brief, that the extent and severity of the disease are not related to climate, isothermal lines, or degrees of latitude and longitude. They are intimately related, rather, to certain social traits in mankind, distinguished in their commercial, military, and religious excursions, trading ventures, pilgrimages, wars, fairs (*e.g.*, that of Nijni-Novgorod), and encampments of armies; their hygienic and medicinal methods; and, more or less in consequence of what precedes, to the density of population and the degree of intelligence possessed by infected classes as displayed in their management of the malady.

Nature of the Disease.—Syphilis is a specific infectious disease, always occurring in consequence of transmission from a diseased to a sound individual, and always transmitted as such. It does not sustain etiological relations with scrofulosis, tuberculosis, leprosy, or any other known disorder. It is capable of transmission by inheritance, and also by the medium of fluids furnished by the pathological tissues of diseased individuals. These fluids when isolated may be said to embody all the power and potency of the disease, and hence are described as virulent, or containing the virus of syphilis.

This virus, or contagious element of the secretion, which may be removed from one individual and artificially introduced into another with the result of thus assuring the complete evolution of the symptoms of the disease, has been the theme of much discussion. Its very existence has been doubted by Bru, Jourdan, and others.

The Bacillus of Syphilis.—After years of research and experimentation, the special micro-organism of syphilis would seem at last to be discovered, though there is yet lacking the production of the disease in man by inoculaton with pure cultures.

Max Joseph and Piorkowski, of Berlin (*Berl. klin. Wochenschrift*, Nos. 13 and 14, 1902), discovered in the spermatic fluid of a male subject, twenty-two years of age, a bacillus 4–8 microns in length and 0.2–0.3 micron in thickness. These were cultivated on sterilized placentæ; they closely resembled in size and other features the diphtheria-bacillus. Transferred to artificial media, there promptly appeared, in twenty-four hours after inoculation, a colony of micro-organisms scarcely visible to the naked eye, producing later a grayish, confluent, agglomerated mass in which, with the aid of the microscope, bacilli were recognized resembling the bacillus subtilis, staining readily with carbol-fuchsin and gentian violet. They were blunt-pointed; usually knobbed at one extremity; and were cultivated on artificial media for three generations; the last produced colonies showing diminution in the size, frequency, and vigor of the bacilli, all of which was materially changed by reinoculation upon blood-serum.

These experiments were verified by examination of the sperm of twenty-two male patients, control experiments with no recognition of the same elements having also been made on sound male subjects. The introduction of pure cultures of this bacillus into a sow was followed by morbid results which, however, might have been possibly due to swine cholera.

Claims to the discovery of a bacillus of syphilis have been made also by Lustgarten, Pisarevski, Klebs, Birch Hirschfeld, and others.

Syphilis without question belongs to the class of infectious granulomata, and is the result of the introduction of a parasite into the human economy. The disease should be classed to-day with tuberculosis and leprosy, the etiological bases of which are now beyond question.

Neisser believes that the bacteria may be transmitted by intra-uterine inheritance or extra-uterine infection at a given point where multiplication of the germs occurs. Whether instantaneous general infection follows by the sudden admission of these micro-organisms into the circulating fluid, or by the slower process of invasion of the lymph-channels and extension through the lymph-glands to the general economy, it seems clear that the initial sclerosis of the disease, a "chancre," becomes a focus of infection which only gradually participates in the same process of distributing the germs of the disease throughout the general economy. Later, the lodgment of these germs in various parts of the body determines the development there of the specific products of the disease; possibly also exercises there that specific local modification which renders the tissue then capable of reacting in a certain characteristic morbid behavior, after the operation of external irritants (mucous patches in the mouth of the smoker, etc.). Neisser believes that the nearer the date of infection, the larger the number of bacteria present at any one moment in the body; and, as a corollary from the above, the more numerous, symmetrical, and superficial the lesions. But in later periods, with a smaller number of bacteria and a gradual decrease in capacity for infection and hereditary transmissibility, there are fewer, deeper, more asymmetrically disposed, and more malignant manifestations of the disease.

Evolution of the Disease.—Between the moment of infection and the earliest appearance of a chancre to the unaided eye, there is usually a delay of from fifteen to thirty-five or forty days, a period of twenty-one days for the average of cases. This is usually called the first incubation. There is, however, neither an incubation, a "hatching," a delay, nor an arrest. If our methods were without flaw, we should be able to detect the movement toward general infection from its very first to its completed step. In the attempt to study the evolution of syphilis, questions of time, the crude hypothesis of an incubation, and all really artificial distinctions, should be, for the purposes of critical investigation, set aside.

By the late eminent Philip Ricord, the evolution of syphilis was divided into three stages, the primary, the secondary, and the tertiary. The primary included the symptoms concerning the chancre and its accompanying multiganglionic adenopathy. The secondary period included the symptoms displayed during the succeeding term, in which systemic infection occurs, with usually symmetrical and superficial cutaneous and other manifestations. This was loosely estimated at about one year in duration. Lastly, following this stage of efflorescence, came the tertiary period, that in which the deeper structures of the body are involved; that in which the disease commonly ceases to be transmissible, in which it may produce its most destructive effects, or pass into a complete innocuousness and decline. The influence of this doctrine of periods has been incalculably great and valuable. It once marked a revolution in the history, in the study, and in the treatment of the disease. It has dominated the minds of the medical men of all lands since it was first completely grasped by the intellect of its master.

But it has served its day. To thoroughly grasp the problems of syphilis, it is now needful, for the time being, to emancipate the mind wholly from the ingenious suggestiveness of this doctrine. It must be clearly seen to be nothing but an artificial device for classifying in a clumsy way the clinical phenomena of the disease.

As a matter of fact, there is no line of demarcation between the successive phenomena of syphilis as they appear in the evolution of the disease in any given case. From the moment when infection has been wrought to that of the gravest injury, or of the mildest efflorescence, there is, when no arrest occurs, a gradual but continuous progression of the disease. This advance is commonly marked by interludes as striking as they are salutary. They may be due to the intervention of treatment, or to changes in the general health of the infected due to other causes. Apparently capricious cessation of the advance of the disease may occur, since even the cutaneous symptoms of marked cases may wholly disappear without treatment. If we were in position to view with keenest scrutiny the unmodified progress of syphilis in cell and vessel, no one can doubt that the so-called period of incubation would disappear and the microscopic eye of the observer would be as busily occupied during that as throughout any other period of the disease. Similarly, there would be no sharp distinction possible between primary and secondary syphilis. One could scarcely note the hour when, from the first to the last, there was not in progress a slow and gradual progression, from point to point, of the toxæmic product originating in the changes wrought at the site and at the time of infection.

These suggestions are needed for a clear comprehension of the phenomena following the stage of so-called "primary syphilis." The "primary" hypothesis made it absolutely necessary to assume that after the primary came a secondary; and after a secondary, an inevitable tertiary stage. More, the mind thus habituated to a study of the evolution of the disease in periods looked to an evolution of symptoms in these periods in due order and line of procession. One was thus educated to expect in a typical and uninterrupted attack of syphilis (could such be observed) each and every one of the several manifestations of the disease. After macules, papules should appear and, in course, pustules, gummata, ulcers, and successive involvement of organ after organ of the body. Some such definiteness of order is, in point of fact, to be recognized in the evolution of variola, with which, unfortunately, syphilis has been too often and too closely compared.

But no such syphilitic history has ever been observed. It is the artificial manikin of the schools, the figment required by the domination of the medical mind by the time rules of the French school. It was this once useful and ingenious time-schedule which made it equally imperative for the French to coin for some of the manifestations of syphilis the striking terms "precocious," "galloping," and "tardy," words which embody a confession of the weakness of the schedule to explain all the exact clinical pictures of the disease.

Almost immediately after lymphatic adenopathy has declared to the eye and the finger of the observer that the toxic product of the chancre site is finding its way into the vascular channels of the body, the phenomena of the disease are evolved, not in the order of a time-card, but, to employ a different figure, in radii from a pathological centre. Early indeed, in many cases, can it be seen that the future of the malady is to be sought along one or another line toward exceedingly variant results. The complexus of these results may be conveniently classified in four divisions, which are named later.

Toward these the advance is either slow or rapid. The gravest may be imminent when the chancre is yet unhealed, the adenopathy unrelieved, the lymphangitis discernible. The mildest may be attained when months have passed, the early accidents are wellnigh imperceptible or forgotten, and the general health of the infected individual meanwhile not manifestly impaired.

Whether this apparent interval (the so-called "secondary period of incubation") be brief or protracted, none can doubt that when an ultimate evolution of the disease occurs there is a continuous progress toward complete or partial systemic intoxication. When well marked, this apparent interval occupies from forty to fifty days, but it has been noted as brief as twenty days and as prolonged as a twelvemonth. Its limits are usually defined between the date of the chancre's appearance on the one hand, and the date of the first cutaneous exanthem on the other. That this is a purely artificial distinction becomes at once apparent when one of these dates of limitation is questioned. There is nothing in a cutaneous exanthem which entitles it to pre-eminence above other symptoms of syphilitic invasion perfectly evident during the so-called second incubative stage. From the date first assigned to the last arbitrarily selected there is no real pause, no conspicuous absence of invasion signs. On the contrary, the symptoms of this period are often more suggestive and significant than when, for example, the skin of the patient's belly is beset with a macular syphiloderm.

The merest enumeration of symptoms possibly occurring in this period of apparent pause is sufficient to indicate that no real incubation can be observed. Yet here again it is important to note that not all of the enumerated symptoms are to be observed in one individual, and further, that they observe no definite order when two or more chance to be parts of one syphilitic history. Rather are they different surface-indications of the several lines along one or another of which the disease may advance toward its ultimate results.

After the chancre appears, and before the first exanthem of general syphilis follows, the condition of the average patient is far from in apparently sound health. The blood-globules commonly decrease, while the leucocytes by actual enumeration increase in number. The glands of the body elsewhere than those in the region of adenopathy near the chancre site, slowly or suddenly enlarge, become tumid, painless, much less indurated than those first noted in the disease, and are often symmetrically, rather than, as in the other instance, asymmetrically involved. The spleen, so intimately is it concerned with the fluids traversing the vascular channels, becomes tumid and at times tender. The liver function is often disturbed, as shown by an icteroid skin with muddy conjunctivæ and the appearance of bile-products in the urine. The functions of the stomach, of the bladder, of the suprarenal capsules, and of other viscera, may be seriously impaired. Continuous or interrupted febrile temperatures may be reached ("syphilitic fever"), the thermometer rising at times even to 105° F., the patient being not rarely treated by a physician ignorant of the nature of the effective poison for an intermittent or relapsing fever. The nervous system may seriously suffer. Atrocious neuralgias, substernal and periosteal pains, pains in the bones and joints, osteoscopic sensations, and even synovial effusions, may be the protest of the system against the advent of the recently introduced poison. Often there are signs of mischief even of a severer type. The lassitude and depression are profound; a condition of mental hebetude gives place to partial syncope; a headache results in a temporary strabismus, a pain in the upper or lower limbs is followed by muscular contracture. None can doubt that in a carefully studied case where the evolution of syphilis is actually in progress, however mild its future is to be, a skilled diagnostician could recognize, at one point or another of the body presumed to be in the stage of this so called secondary incubation, unmistakable evidences of an insidious advance of the malady.

The term "explosion" has been repeatedly employed, with other metaphorical phrases, to describe the moment when the first cutaneous exanthem appears. Its use is an index of the extravagant importance attributed to the onset of skin-symptoms in early syphilis. As a matter of fact, the latter are surface indications of more serious and deeper processes (probably involving the nervous centres) and are all-important to the eye only of the vulgar. As a matter of fact, too, they never occur by explosion. The first efflorescence of the disease may be as gradual as the dawn of a day and as impossible to define. Before the human eye traces its first expression, the camera of the photograph can produce with fidelity the faint mottlings of a skin that is to be later visibly the seat of a syphilitic efflorescence. No one who has with minute care watched the oncoming of the cutaneous manifestations of the disease, can have failed to note how insidiously the approach is made to the eye. An accident may change all. The excessive heating of the body in a bath or by dancing may simply precipitate the blushing of the first rash.

This once apparent, and let it be noted even without this, syphilis exposes its advance in numberless directions, probably in no two cases exactly the same. These advances may be, however, for practical purposes, classified in four principal directions, as previously suggested in these pages. They may be named and briefly sketched as follows:

1. Benign syphilis with mild and transitory symptoms.

Every vacciniculturist has recognized the fact that a few heifers fail to respond to all efforts to inoculate the udder with vaccinia. The reason is not explained; the system of a few individuals in every thousand simply refuses to react against the introduction of the poison. No expert of wide experience can fail to have been impressed with the fact of the existence of this exceptional class of human subjects with respect to syphilis.

There are persons who exhibit typical chancres with characteristic adenopathy of the vicinage, who never after exhibit the slightest signs of systemic disease. The objection to this statement is suggested at once to the mind of the profane. It is, that an error was made in the diagnosis of the initial sclerosis. That which seemed to be a syphilitic chancre was really not such, but spurious, an imitation of the genuine lesion. But, it is responded, such chancres have been not carelessly, but with exquisite skill, studied by experts, and found not different from others followed by grave syphilis. Further, the persons enjoying this immunity have failed later to contract the disease when exposed to it; and, more important than all else, individuals of this class correspond to others of the same class who, having actually exhibited such chancres, do later have systemic symptoms of such mild type as to astonish those unfamilar with these singular exceptions to the rule.

These interesting exceptions are either the triumphant proofs of the skill of the physician, or (what is far more probable) proofs that some of the phenomena of natural law defy ultimate analysis by the human mind. Persons of this class have typical, severe or mild, premonitory chancres. In due time they have also slight ganglionic engorgement, post-occipital, along the nucha, or in the line of the sterno-cleido-mastoid muscle. An exanthem occurs, of macular type, upon the belly, over the chest, slightly upon the face, or perhaps limited to the trunk. When this fades, with or even without medical treatment, the disease is absolutely at an end. These cases are annually observed in every extensive syphilitic practice. They are not rarely seen in women who have been infected without their knowledge by a husband, or through the innocent contacts of daily life.

2. Benign syphilis with relapsing or persistent superficial symptoms.

Cases assignable to this category are those in which typical chancres are followed by typical early manifestations of general syphilis, the patient continuing, for months or even years after, to be annoyed by intractably persistent or relapsing, but wholly superficial syphilitic symptoms. If described according to the former phraseology, these would be classed with the subjects of prolonged secondary syphilis, never proceeding to tertiary stages. Two, three, and four years after infection, such subjects are found with an infiltrated patch of scaling papules on buttock or back; with mucous patches of lips, tongue, or fauces; with a squamous scrotal, palmar, or plantar syphiloderm; or with a cluster of superficial and crusted papulo-pustules over the occiput or temple in the pilary region. After alternately trying and tiring of all methods of treatment, the disease at last yields. Throughout all, from first to last, there is no sign of a formidable malady. When recovery has at last occurred, no trace is left on the body of the infective process. There has been no deep ulcer, no cicatrix, no permanent impairment of any organ or tissue. The disease, viewed in retrospect, has been perhaps a long but always rather an annoying than a dangerous affection. It may never have for a day prevented attention to the routine work of the sufferer. Had it not been for the incidental apprehension of the future, it would not have attracted serious attention nor demanded assiduous care.

Such, without any question, is the course of the majority of all cases of syphilis. It is claimed that, however mild these histories, each is liable to result in the graver forms of the disease, and that which determines the difference is treatment, always of highest importance. The most superficial study of syphilitic statistics, however, demonstrates that the majority of all patients, with the best, with the poorest, and without treatment, escape what has long been termed tertiary syphilis; in other words, do not exhibit the destructive types of the disease. The percentage of the latter to the former, in both hospital and private practice, has been estimated at the lowest at about seven per cent., at the highest at nearly thirty per cent. The corollary, therefore, is trustworthy that at the least two-thirds of all patients in all countries, and subjected to all methods of treatment or none (homœopathy, ignored cases, expectant treatment, "mind cure," etc.), escape the destructive ravages of the disease. It is upon this issue in the majority, and not upon the dreaded results in the minority, that the evolution of syphilis in the average of cases is to be predicated. Nothing that is here set down is to be interpreted in denial of the equally palpable fact that the mildest case of syphilis at the outset may become the severest in the end; that the patient fairly launched in the direction of benignancy may be mischievously turned in a different and more dangerous course; that scientific treatment of the disease furnishes one of the greatest triumphs of human ingenuity and skill. It is here intended merely to look at the results of the evolution of the disease, among all classes of men and in all countries, from the broadest point of view.

3. Malignant syphilis with relapsing or persistent profound symptoms.

A recent French writer has well distinguished between the syphiloma that resolves and that which degenerates. In this third category are included all patients exhibiting gummatous lesions that are either resolved and do not return, but leave serious consequences behind; or that are resolved and return later with serious consequences after either or all outbreaks; or that persist with no less harmful results. Here, too, are variations from the less to the more dangerous grades.

Any one of these conditions may develop after the patient has exhibited only such lesions as would justify his being classed in the category just considered. But it is highly important to note that all the symptoms here described and catalogued may succeed the chancre stage without intervention of milder symptoms, and also without an important interval of time. Early, indeed, after the chancre has healed, often before this last is completed, there are indications of the evolution of the disease toward a malignant type.

The "malignancy" of this class of cases is seen in the deterioration of the general system and the production of a syphilitic cachexia, without absolute destruction of the tissues of the body. Gummata that never ulcerate or degenerate may form in the skin, subcutaneous tissue, bones, periosteum, periarticular and articular tissues, mammary gland, testis, or other organ. By the production of pain; by displacement or mechanical effects; by a subtle influence, that is difficult of analysis, on chylopoësis, sanguification, or nutrition, and by interference with other functions, a disastrous influence is exerted that justifies the term malignancy in describing the course of the disease. Its effect is most striking when the structural lesions are few and not in themselves grave. A patient with merely a submaxillary lymphoma or periosteal gumma, or with an obstinate pachymeningitis producing injury by pressure-effects rather than by destructive action, may be in a graver physical state than another with a profound ulcer of the leg or of the throat.

In this category are to be found the smaller number of all cases of syphilis. It is pre-eminently the category of the transitory. They who have suffered from a syphilis trending along these lines, either by force of good management or as a result of the self-limiting energy of the disease, or the reverse of these, are readily transferred to the class just described or to that which is considered below.

4. Malignant syphilis with relapsing or persistent and profound lesions that are ultimately destructive.

In this category are classed all those patients who exhibit the worst phases of what is called by the French "tertiarisme," the symptoms which have made the disease to be dreaded as much as any of the pestilences that have visited destruction upon the human family, the histories which have engendered the popular and quasi-professional belief in the non-curability of the disease, those which have led philosophers to wish that the disease were one that kills, rather than one that can so frightfully mutilate without killing.

Here the resolving or disintegrating gumma opens an avenue to ulceration that pierces through connective tissue, cartilage, periosteum, and bone; to resorptive results which, when the gumma has disappeared, leave in its site shrivelled secreting cells, nervous, hepatic, renal, osteoid; that leave the testicle a shrunken miniature of its former self; that leave a sclerotic tissue in the place of brain cells or spinal cells, whereby one-half of the body loses its motor function, or a portion of the brain its ability to preside over the function of speech. Here, too, remote as are these formidable consequences on the time-schedule of the French school, all are obliged to admit that but a few weeks may intervene between the chancre evolution and the worst ruin. In a few days, while yet the induration of the chancre persists, the hard palate may be perforated as readily as the finger may be pushed through a sheet of wet paper; or a liver may be stuffed with ominous nodules; or the surface of the body ploughed here and there with deep and even gangrenous excavations where a gummatous infiltration has rapidly melted to destruction. It is true that for the most part these grave results occur between the third and fourth years after infection; but the facts of early appearance of so called late symptoms in syphilis are by none better attested than by the French themselves. It is they who have coined for science the phrases "malignant precocious syphilides" and those of similar import. It is they who freely admit that the malignancy and precocity are in these cases intimately associated. It may even be asserted as a fact that the majority of all truly malignant manifestations of syphilis are precocious to the extent of violating the old rule of tertiary syphilis as a sequel of an orderly and classically developed secondary stage. It is the characteristic of these dreaded devastations of the malady that they are early declared and rapidly evolved as extremely formidable types rather than as dangerous complications or perilous sequels of lues. Even with the chancre unhealed, the surface of the body may be in these cases riddled with sloughing cavities.

Between the four main lines of evolution briefly delineated above, there are to be recognized clinically innumerable variations in the direction of both mild and severe symptoms. That these types mutually merge and are to a degree interchangeable by the accidents of environment, constitutional influences, and treatment cannot be questioned.

An examination of the symptomatology in 96 cases reveals several points of interest. The organs affected were, in 47 cases, the derma, subcutaneous, and adjacent tissues; in 11, the bones and periosteum; in 11, the brain and cord; in 7, the soft and hard palate; in 6, the tongue; in 7, the testes; and in one each, the vulva, the eye, the kidney, the rectum, the muscles, the lungs, and the joints. Fournier, of Paris, reported before the International Congress of Syphilography and Dermatology in Paris, in the year 1889, the fruits of twenty-nine years of private practice in the French capital. In these twenty-nine years he had been able to study 2,600 cases of tertiary syphilis occurring in private patients. Some of his results were in the highest degree confirmatory of the important data of tertiarisme given above. But he also demonstrated that among 3,429 instances of tertiary manifestations, he had tabulated 1,085, or nearly 32 per cent. of cases, in which there was some involvement of the brain and cord. Haslund, of Copenhagen, has studied patients treated in the Communal Hospital of his city. Of 514 cases of tertiary syphilis observed by him there, there were 133 in which there was involvement of the nervous and other systems, or a percentage of the latter to the entire number of cases of 25; while the derma was implicated in 290 cases, a percentage to the whole of nearly 60. Among Americans the statistics of private practice indicate that the nervous system is involved in but a trifle more than 13 per cent. of all forms of tertiary syphilitic manifestations under observation; while the derma and its connections were implicated in about 60 per cent. of all cases.

The recognized elements of importance in grave syphilis are, first, the constitutional condition of the patient. Malnutrition from whatever cause produces a marked decrease in the weight of the subject; and it is also true of the excessive weight of patients who are more fleshy than the average, a class in private practice decidedly outnumbering the others.

Second in importance, and often indeed co-operating with the cause already named, may be named the agencies producing debilitating effects upon the system, including among men alcoholism and excessive tobacco usage. All other debilitating agencies (anxiety, affliction, overwork in business or profession), all that engender anæmia, loss of vigor, neurasthenia, are here properly included.

At the foot of the list should be placed complete absence of treatment, insufficient or injudicious treatment, and even intolerance by the patient of mercury.

Syphilitic Chancre (Initial sclerosis of syphilis; Hard chancre; Infecting chancre).—After exposure to the active virus of syphilis there is commonly a period of delay before the first perceptible symptoms of local infection occur. This period, usually described as the first "incubation stage," extends on an average from about sixteen to thirty days, but it is claimed that exceptional cases occur in which it may be as brief as two or three days only, or prolonged beyond the larger number days named above.

The resulting chancre which therefore, in acquired syphilis, points to an infection occurring within the month preceding its appearance, develops at the site of introduction of the germ of the disease, and may occur in many types according to its location and the accidents of its environment. There is no single lesion, the appearance of which invariably signifies that a chancre is present.

Every chancre is characterized: First, by the delay after infection before it appears (described above); second, by a characteristic induration, or hardness, of its base; third, by a coincident or succeeding enlargement of the glands in proximity to its site, the "syphilitic bubo."

A chancre may be either a modification of the normal tissue of the skin or mucous membrane, or a modification of any possible morbid condition, such as a cigarette burn of the lip, an excoriation of the mucous membrane of the genital or progenital region of either sex, etc.

In general, the clinical features of chancres correspond more or less closely to the following types:

1. *Erosions*, or superficial roundish or irregularly outlined macules, shallow losses of the superficial layers of the skin or mucous membrane, reposing on delicate beds of induration. The type of the latter is that often described as "parchment induration," the sensation it produces to the fingers of the surgeon, suggesting that a thin sheet of parchment has been let in under the excoriated surface. These may be pin-head- to bean-sized lesions, dry, or scantily secreting and slightly moistened, very rarely indeed, unless greatly irritated, degenerating into ulcers. For the reason that they may have an innocent aspect, they are often misinterpreted, but they should always be regarded as the precursors of syphilis when accompanied by the characteristic bubo of that disease.

They may be complicated by the occurrence of very considerable induration or may be transformed into large flat elevations of the surface, suggesting condylomata, but readily differentiated from the latter by their exceedingly dense induration; and when cauterized or otherwise improperly treated, they may even ulcerate, a change for which they have no aptitude when pursuing their usual career. They are occasionally represented by odd-looking ridges (along the corona glandis or at the rim of the labia minora in women); by thickenings of the membrane at the tip of the glans (urethral chancre); or by a firm and circumscribed thickening of a limited part of the upper or lower lip of the mouth.

2. The *dry papule* is of commoner occurrence on the skin of the body elsewhere than that of the genital region, as of the arm after intentional or accidental inoculation. The chancre is then a pea- to lentil-sized, dry, scaling, and indurated papule or papulo-tubercle, with dirty-grayish scales at apex or base. It is at times seen over the pubes, near the anus, on the integument of the pendulous portion of the penis, in the groin, etc.

3. The *ulcer* is decidedly the rarer type of chancre, and may be said to result invariably from some accidental interference with the normal evolution of the process occurring at the site of inoculation, such as pus infection, admixture with the virus of "soft chancre" (*q.v.*) or improper treatment. Both shallow and deep ulcers may form, each with sloping edges, never exhibiting the clean-cut, sharply defined edge of the chancroid. These ulcers are at times represented by indurated fissures or cracks. The so-called "Hunterian chancre" is a huge crateriform excavation of a densely indurated mass of sclerosis. This sore, which Mr. Hunter supposed to be the sole precursor of syphilis, is merely an altered lesion of one of the types already described. Other chancres of unusual type and appearance have been described as "diphtheroid," "herpetiform," umbilicated, "silvery spots," diffuse infiltrations, indurated nodules, annular and encrusted lesions, all these terms describing merely accidental modifications of the lesion occurring always with the three invariable characteristics already enumerated.

The "mixed" chancre is that in which the virus of both syphilis and the chancroid are commingled in the production of a lesion which at first assumes the aspect of the chancroid without the lapse of the usual incubative period of the infecting chancre; and later, after that period has lapsed, takes on the usual characters of the initial sclerosis.

THE STAGE OF INVASION OF SYSTEMIC SYPHILIS.—After the appearance of a chancre, from forty to fifty days usually elapse before the appearance of the first syphilitic eruption. This period may be shortened to three weeks; and, in exceptional cases, prolonged to several months. There is strong reason to believe that it may be prolonged under the influence of mercury. In it the chancre commonly progresses from complete evolution to involution; and, when there has been ulceration of that lesion, to cicatrization. Usually, also, when ten or fifteen days only of this period have elapsed, the adenopathy connected with the chancre has appeared and reached its full development. With the chancre healing or cicatrized, and with one or several of the neighboring glands, possibly their lymphatics also, in a state of painless induration, the concluding three-fifths of this period is one of apparent inactivity of the disease. It has been called for that reason a second incubative period of the disease. In the view of the inexperienced, the subject of the disease at this time may be possibly regarded as in a condition of health. Careful examination, however, reveals usually the following significant symptoms:

(*a*) *The Chancre Features.*—If the chancre be examined it will be found, if recognized at all near the conclusion of the period, either ulcerated, cicatrized, represented by a sclerosis, or preparing for transformation to a lesion of secondary syphilis. Sometimes a deeply ulcerated and formidable chancre persists as such till the complete evolution of secondary syphilis; oftener, before the date of such evolution, a previous ulceration has resulted in a tender cicatrix surmounting one of the several grades of induration which characterize the primary lesion. In yet other cases, without any distinct ulceration, the characteristic sclerosis of the disease persists (upon the genital region, finger, lip, etc.), ranging in bulk from a parchment-like thickening to a large nut-sized semi-solid mass usually freely movable upon the tissues beneath. Careful search for this sclerosis in every suspected region should be made in all first examinations of a patient at this period. In yet other cases the chancre is represented by an erosive lesion capping any form of sclerosis which, participating in the process of systemic evolution of symptoms, soon exhibits an elevated floor which may be covered with a whitish pellicle resembling the surface of a mucous patch, and be thus in fact changed to a true granulating mucous patch, the so-called transformation of chancre *in situ*. In all or any of such events, just prior to the evolution of secondary syphilis, there is often a marked, pathological activity of some sort in the chancre-site, the sclerosis becoming larger, the declining maculo-papule more vivid, the ulcer deepening or reopening, or the superficial erosion becoming a smooth, granulating surface with an opalescent pellicle spread over its area.

(*b*) *The Lymphatic Glands and Vessels.*—With very few exceptions one or more, usually several, of the lymphatic ganglia nearest the site of the chancre are found enlarged and indurated in this invasion period. From the tenth day after the appearance of the primary lesion to the conclusion of the invasion stage (that is, the date of appearance of the first syphiloderm) these symptoms persist. In general, it may be said that the first half of this period is required for complete evolution of the local adenopathy which in the latter half may be somewhat less conspicuous, but which yet often, at the termination of this stage, exhibits the evidence of pathological activity described above. In some cases the glands become swollen, tumid, and tender at the onset of general symptoms. The induration of the glands may persist afterward for months, the duration of the syphilitic bubo depending somewhat upon the treatment pursued. Suppuration of these indurated glands is very rare. The lymphatic vessels in anatomical connection with such glands may also undergo this specific induration, and be represented by dense quill-sized cords, single or multiple, reaching from the site of the chancre to the single lymphatic gland or cluster of glands which are superficially involved.

Besides this persistent indurated condition of one or several of the glands near the chancre site, noticeable in the invasion stage of general syphilis, there is usually appreciable toward its conclusion a remarkable and often suddenly occurring engorgement of the superficial ganglia. This symptom is not of local but of systemic importance. It is related less to the chancre than to the general oncoming syphilis. It is an early and almost constant symptom of general infection, often, as just described, particularly conspicuous prior to the evolution of the first syphiloderm; at other times, not fully developed till such early symptoms have been declared, and in both cases usually persisting for some weeks after its appearance.

Reference is made to a tumid and engorged, very rarely indurated, often softish condition of the chain of lymphatic glands extending along the posterior border of the sterno-cleido-mastoid muscle, or of the post-auricular, suboccipital, epitrochlear, or submaxillary glands. These glands, usually so small as to be scarcely recognizable by the finger passed over the skin, may increase till they are of the size of a bean or a small nut, and are even conspicuous to the eye of the observer. The two glands beneath the occiput are often very significantly enlarged in this way, irrespective of the occurrence of any lesion upon the scalp or vertex. This general engorgement of certain special lymphatic ganglia is often symmetrical, the glands, for example, behind one ear, or over the mastoid process, corresponding in size and firmness to those of the other side of the body. Occasionally this engorgement of glands in special regions of the body is proportioned in extent to the syphilodermata developed in continuous regions, of the scalp, for example, where the suboccipital ganglia are affected.

(*c*) *State of the Blood.*—Syphilis, though popularly known as a "blood disease," is actually one in which but few alterations can be demonstrated in the blood. Investigators have, by repeatedly counting the number of red blood corpuscles, determined that these elements, in certain stages of syphilis, are reduced from fourteen to fifty per cent. in number. With this decrease in the red blood corpuscles, there is relative increase in the number of leucocytes. This change is characteristic of the early stage only; it is especially noticeable just prior to the evolution of the first syphiloderm. In the period under discussion the micro-organisms which produce the disease are multiplying, and by the avenues of all the vascular channels gaining access to distant parts of the body; even to regions where later a gummatous product may form.

The chloro anæmia which is the result of systemic intoxication in syphilis occurs from time to time in most well-marked cases of the disease. It may be an early or late symptom, and in grave and so-called galloping cases is throughout a marked feature of the malady. In tertiary and ulcerative types of syphilis, it may depend more upon the local symptoms than upon the general condition, and, in some cases, is without question a resultant of the long-continued inroads of the poison upon the general health. Justus has shown that in the early stages of syphilis a decrease of from ten to twenty per cent. occurs in the hæmoglobin blood-content twenty-four hours after mercurial inunction of the skin.

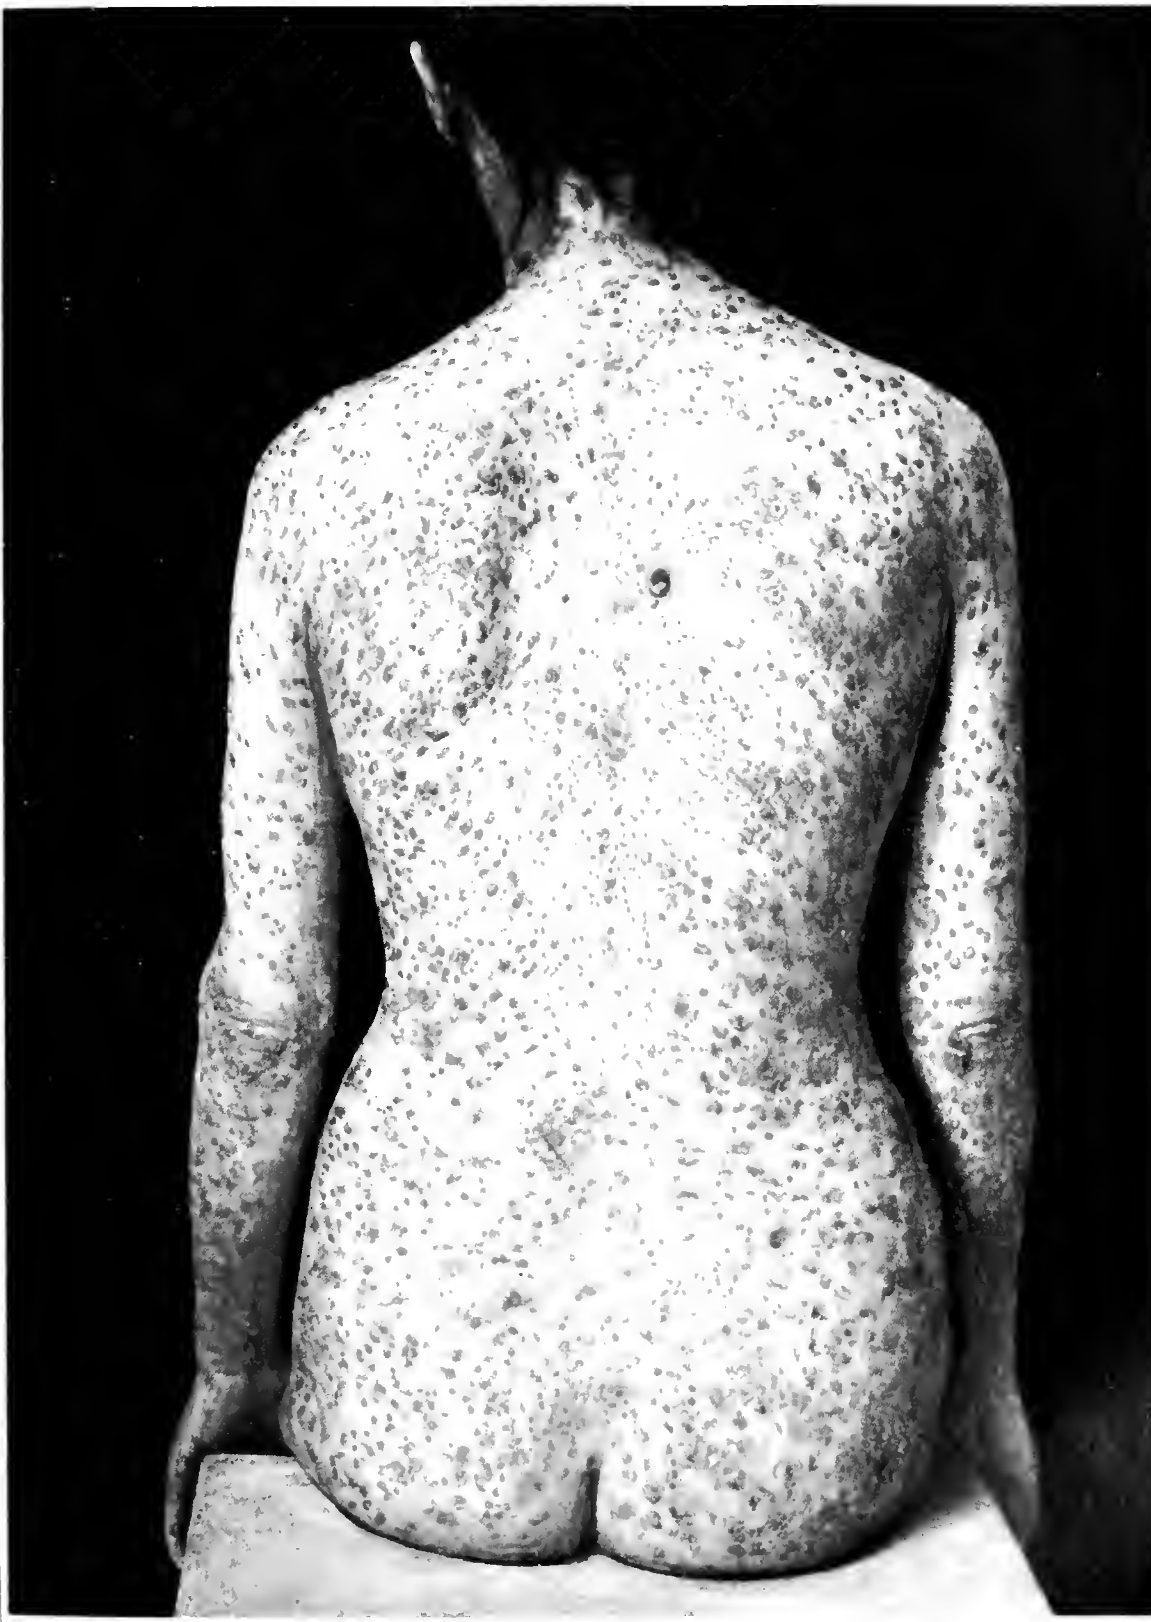
This chloro anæmic, anæmic, cachectic, or asthenic state is often conspicuous in the invasion period now under consideration, with mild or grave symptoms, particularly in persons of a naturally weak constitution, or in those prostrated by other previous disorders. Often, just before the appearance of the earliest syphiloderm the patient exhibits a pallor of the face, accompanied by a discolored, muddy, leaden, or saffron-like tint of the skin. With this there may be emaciation, weakness, and vague rheumatoid pains in different parts of the body (substernal, plantar, temporal, tibial, etc.). There is anorexia, and the patient will often describe his condition as one of "biliousness." In exceptional cases there is decided icterus, with yellowish conjunctivæ and urine of high specific gravity and heightened color. With this condition may be associated the ganglionic engorgement already described; the characteristic induration of the glands nearest the chancre; and the persistence of the initial sclerosis as a dense ridge, button, plaque, nodule, agglutination of tissue (digital chancre), or thin circumscribed sheet ("parchment" form of induration).

(*d*) *Syphilitic Fever.*—Recurrent, remittent, more or less persistent, and even intermittent elevations of temperature are of frequent occurrence in syphilitic subjects, more particularly in the early stages of the disease.

From one week to a fortnight before the first syphiloderm appears, with and without the icteroid, cachectic, or anæmic hue of the skin described above, the bodily temperature may rise to any point from 101° to 105° F., the lower figure representing the average of all cases where any such form is recognized by the physician, the higher temperatures often coinciding with a tolerably profuse first exanthem of syphilis. Usually this is a transitory symptom of the disease; but at times it persists for weeks. In cases, it is preceded by a sensation of chilliness or by distinct rigors. When remittent, the exacerbation is usually vespertine. There are commonly coincident thirst, malaise, *courbature*, and osteoscopic pains with headache and backache. In some cases, the febrile state is so insignificant as to attract no attention.

SYPHILODERMATA (Syphilides, Cutaneous lesions of syphilis).—The skin-symptoms of syphilis are numerous, widely different in type and career, and of the highest importance in the diagnosis of the disease. In any given case of syphilis, the greater number of skin lesions are displayed during the first two years after infection, that is, during the so-called secondary stage of the disease. They, however, occur often in grave forms in the late or tertiary period of syphilis.

General Characteristics of the Syphilodermata.—The skin-lesions of syphilis resemble the skin lesions of almost every non-syphilitic disorder, yet differ from the latter in certain special features. The study of these differences is essential to the recognition of the identity of the syphilitic exanthem. Their characteristics, generally considered, may be classed as follows: 1 Absence of subjective sensations. For the most part the syphilodermata are not accompanied by pruritus, or by sensations of burning, heat, pricking, etc. Notable exceptions to this rule may be found, but it is fairly constant of application, and due to the chronicity of the syphilitic exanthemata, their remarkable tendency to recurrence, and their striking amenability to treatment. 2. Career. The syphilodermata are rarely pyrexic; their course is essentially chronic; they are exceedingly liable to recur; and yet, as distinguished from the lesions of epithelioma and lepra, they are relatively rapid in evolution. They are greatly influenced by treatment, and are hence rarely seen when unmodified; but it is highly probable that all of them have, within variable limits, a cyclical career which would be pursued in most of the cases if no interfering agent modified their evolution. 3. Polymorphism. Multiformity of lesions—that is, the occurrence of multiple lesions of different elementary forms at one time upon the same person—is characteristic of several diseases of the skin, including syphilis. In the latter, papules, tubercles, pustules, ulcers, and maculæ may coexist upon the skin of an infected individual, who thus presents a striking contrast with the psoriatic patient, for example —the skin of the latter being often extensively covered with exclusively squamous lesions. 4. Color. The color of a cutaneous exanthem differs not only in different individuals of different color-type (blonde, brunette, African, etc.), but also in the same individual from year to year. This is true of the syphilodermata, the color of which exhibits the widest range of differences under different circumstances. Certain combinations, however, of the brown, the purple, and the duller hues of other colors are especially striking when seen in syphilodermata that are typical also in seat and configuration. The so-called characteristic color of the syphilodermata has been compared with that of raw ham and of coffee, shades which, when at all distinct, are highly suggestive. (See Plate LIII.) After complete involution of many of the syphilodermata, especially those seated on the lower limbs, the deeper pigmentations, suggesting chocolate, coffee, or ink in color, are often recognized. Most of these deeper tints are gradually and completely removed in the months or years that succeed complete involution of the lesion. 5. Contour. Many syphilitic lesions of the skin have a remarkable tendency to assume, wholly or in part, when grouped, a circular outline. This contour is often preserved when there has been both a grouping of elementary lesions and subsequent metamorphosis or degenera-



tion of the lesions thus grouped. In this way the figure of eight, the letter **S**, the dumb-bell, the kidney, and the horseshoe may be represented in outline by syphilitic papules in groups, ulcers, crusts, and even cicatrices. 6. Site. Any part of the skin of the human body may become the seat of a syphiloderm; and, indeed, the entire surface may be thus invaded, either by simultaneously evolved lesions or by rapid extension from one point to another. Syphilis may, however, affect for long periods of time a single region of the skin exclusively. This region may thus be preferred as the result of local irritation; for example, the palms of the syphilitic hand-worker, the uncleansed anal region of the syphilitic infant, and the mouth of the syphilitic tobacco-chewer. The so-called "corona veneris" is a group of dull-reddish, scaling papules on the forehead, which are peculiarly significant in male patients where the lining of the hat irritates the brow. 7. Amenability to Treatment. Mercury more particularly, and to a less extent the salts of potash after ingestion, are regarded by many practitioners as tests of the syphilitic character of any exanthem. There are few eruptions which amend under treatment of this character as readily as do the syphilodermata, but it is an error to conclude that the latter only are thus manageable. The great variability of the skin pictures in syphilis is largely due to modification by appropriate therapy. 8. Character of individual lesions. The scales of syphilis are rarely lustrous or nacreous; they are commonly small, dirty-gray, or darker in color, and rarely very abundant. Syphilitic papules are small or large, but often remarkable for a collarette of dirty, whitish scales surrounding their bases. The crusts of syphilis are apt to be dark-hued, in shades of deep yellowish, greenish, chocolate, and black, in consequence of the tendency of many syphilodermata to ulcerate and from the production in such ulcers of the pus and blood from which these colors are chiefly derived. The oyster-shell-like crust of rupia is wellnigh pathognomonic of syphilis. Syphilitic ulcers are prone to exhibit the circular outline, or traces of the reniform, figure of eight, letter **S**, and other shapes named above. The cicatrices left by such ulcers have necessarily a similar contour. They are, for the most part, smooth, supple, soft, and unattached. When recently formed, especially on the lower extremities, they are deeply pigmented in shades of chocolate and black. All, however, in time become white and lustrous, suggesting a thin sheet of mica when the centrifugal decoloration, which each very slowly undergoes, is complete.

THE MACULAR SYPHILODERM.—(*a*) *The Macular Syphiloderm due to Hyperæmia* (Erythematous syphilide; Syphilitic roseola; Exanthematous syphilide).—This is usually the earliest of the eruptions of secondary syphilis commonly appearing about forty-five days after the appearance of the chancre. It is developed in the form of symmetrically arranged, roundish, oval-shaped, or irregularly outlined, from the size of a split pea to that of a small coin, non-elevated, rosy, reddish-yellow, dusky red, or salmon-and-red maculæ, disappearing under pressure. Often at the outset this exanthem most resembles a slight mottling or marbling of the surface, and at times requires for its recognition careful observation on the part of the physician. It is probably more often unnoticed by the patient than any other symptom of syphilis, at times escaping observation entirely. It may be generalized, but is usually most conspicuous on the belly, loins, chest, and back. In well-marked cases the face (brow, temples, chin), back of the neck, and extremities, including the palms and soles, are conspicuously involved. It may be accompanied by the syphilitic febrile symptoms already described, substernal and other pains, engorgement of the cervical ganglia, mucous patches of the mouth, and other symptoms peculiar to this period. It may persist for a week and fade; or recur in fresh maculations. As the eruption survives, it is more persistent in color under the pressure of the finger. It is decidedly and promptly amenable to mercury. It is not to be confounded with the exanthematous fevers (the thermometer readily indicating the difference); nor with urticaria and the medicamentous rashes, which are more acute in type and accompanied by well-marked subjective sensations; nor with the yellowish patches of tinea versicolor, where a vegetable parasite is visible under the microscope. None of these affections exhibits the other signs of syphilis present in the person displaying the erythematous syphiloderm. The chief diagnostic danger, however, in this connection lies in ignoring, in certain cases, the special character of this indolent, scarcely appreciable exanthem, which rarely attracts attention by subjective annoyance, rather than in any difficulties in determining, after its discovery, to what special disease it is due.

(*b*) *The Macular Syphiloderm due to Pigmentation* (Pigmentary syphilide).—This exanthem occurs in an irregularly circular, ill-defined reticulum, of brownish or chocolate-shaded maculations, the color of which does not fade under the finger. Often there is unusual whiteness about the pigmentations, centrally or peripherally situated. Dr. Fox, of New York, has shown that after the central pigmentation develops there is a centripetal decolorization with deposit of pigment in excess in the interspaces of the original maculæ. The eruption is common about the neck and shoulders of blonde women. Illustrations of this condition in concentric circles of large pinhead-sized maculæ, alternating with rings of pigment, may be seen in Chinese subjects of syphilis. The lesions are obstinate under treatment, and are often included among the doubtful exanthemata of the disease. They are pigment anomalies, occurring in syphilis as in other diseases influencing the nervous centres.

THE PAPULAR SYPHILODERM.—The papule is the type of most of the syphilodermata. Many of the others are evolved from it; and it is probable that a large proportion of chancres and most mucous patches, condylomata, tubercles, and similar lesions are essentially papules which have been modified by the accidents of site, moisture, heat, etc. Syphilitic papules are circumscribed firm elevations of the surface, ranging in size from a millet-seed to a split pea. They may occur as the earliest cutaneous symptom of the disease in its earlier stage, or be developed from the macular syphiloderm described above. They may be small or large, pointed or flat, disseminated or in groups.

The Small Acuminate, Papular Syphiloderm ("Syphilitic lichen," Miliary papular syphilide).—This eruption appears in the form of pointed, firm, circumscribed papules the size of a pinhead or of a millet-seed, often copiously developed, with or without febrile symptoms, over the belly, chest, arms, back, and extremities, and usually in defined groups. The eruptive elements vary in color from rosy reddish to mulberry or purplish hues, differing widely in light and dark skins. Often the outer layer of the stratum corneum of the epidermis is slightly separated about the individual papule, which is thus surrounded by a faintly defined collar of scales. Often, also, when irritated they exhibit a minute vesicle, pustule, or scale at the apex. Where numerous, they are often symmetrical and very closely set together. Brownish-red blotches may follow their involution. The eruption may persist for months, and, with or without relapses, may appear in circular or semicircular groups, a ring of minute papules partly or wholly surrounding a confluent central patch.

The Large Acuminate, Papular Syphiloderm.—The small lesions described above may be, in special localities, developed to lenticular dimensions, retaining the conical apex. They may be seen on the back, shoulders, and chest as purplish-red rather than bright red papules, especially in the coarse skins of male patients. They may develop at the apex minute pustules, the involution of which leaves a small crust cap. They should not be confounded with iodic acne.

The Small Flat, Papular Syphiloderm.—This eruption is made up of roundish or oval, reddish to deep brownish, distinctly circumscribed and softish papules, from the size of a large pinhead to that of a split pea, and having a flat surface. They are often seen on the chest, face, buttocks, extremities, and palms and soles, and are frequently found near the mucous outlets, though decidedly less often grouped about the mouth and nose than are other lesions to be described later. They may be few, or developed in a copious exanthem. They may be covered with a thin seborrhœic crust, after the removal of which is exhibited one of the characteristic and almost indescribable color shades peculiar to syphilis, a lucent mixture of red, brown, and purple, suggesting the varnished section of a raw ham. They may be fringed or capped with scanty, dirty-yellowish scales. This eruption rarely occurs in cachectic subjects with a diphtheroid deposit over the papules, covering thus a granulating or superficially ulcerated surface.

Cicatrices seldom follow the involution of the syphiloderm under mercurial treatment. It commonly requires a week or ten days for complete development and, though occurring as an early syphiloderm, may relapse in any stage of the secondary period. Circinate groups, with an unchanged central area of integument, are rather more distinct in relapsing than in early forms of the exanthem. These are readily distinguished from psoriasis by the absence of the abundant nacreous scales of the latter disease, with a history of clearing, not of a primarily cleared centre.

The Large, Flat, Papular Syphiloderm.—This eruption appears in the form of distinctly circumscribed, vivid or purplish-red, flat or slightly globoid papules, discs, "buttons," or nodosities, from the size of a pea to that of a small coin, many of which distinctly exhibit the quality of color seen in a new copper penny. They may become scaly at the surface or the base, or become granular, moist, and secreting in these situations. They are insensitive, and rarely productive of pruritic sensations. The exanthem may be developed primarily, or be evolved from the macular lesions, or, very conspicuously and commonly, in the exanthematous period of syphilis, with a primary or relapsing and abundant crop of lesions in some special locality—the face (alæ of nose, forehead, mouth), palms, soles, axillæ, buttocks, and extremities. Upon the forehead these lesions may form the so-called corona veneris, glazed papules of coppery hue, arranged often in a line above the brows. They may develop an elevated rim and sunken centre; may ulcerate, especially in cachectic subjects or in localities subject to unusual moisture or irritation. Rarely gyrate and serpiginous lines of these papules are to be seen in special localities, *e.g.*, about the non-bearded lips and chin, or the axilla, where they may form rings. They are to be distinguished from isolated psoriatic patches, circinate in outline, (1) by their dull color, as distinguished from the more vivid hue of psoriasis; (2) by their scanty dirty-hued scales; (3) by the history and concomitant symptoms of syphilis.

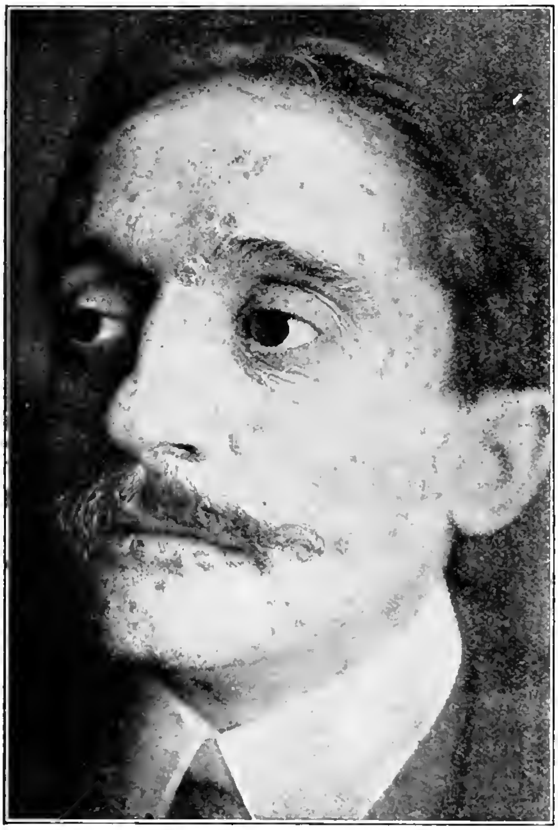


FIG. 4586.- Large Papulo-crustaceous Syphiloderm of the Face.

Syphilitic papules of all types may undergo any one of the following transformations, the features of which may often be recognized at one and the same time in the course of the disease:

1. The evolution of papules may, as a result of hyperplasia or vegetation, proceed to the production of the larger lesions recognized under various titles—warts, papillomata, condylomata, frambœsioid verrucæ, etc. In this way isolated or confluent, softish, warty growths, light or deep reddish in color, freely furnishing a secretion, often of nauseous odor, may cover large surfaces of the body or a single region only (scalp, anus, genitalia). These may be crusted from desiccation of the puriform mucus which smears them; in other cases ulceration ensues.

2. The evolution of the papules, as a result of the same processes in special situations, results in the production of broad, flat lesions. These are the results merely of an hypertrophic process occurring where mucous or cutaneous surfaces are in such close apposition that elevation of the lesion is restricted and lateral expansion only is possible. In this way are produced the condyloma, and the pinkish, whitish, and softish lesions known as the mucous patch of the skin, the vegetating mucous patch, *plaque muqueuse*, etc. They are well-defined, slightly raised, flattened discs, from the size of a bean to that of a large coin, their whitish color largely due to the muco-purulent secretion with which they are smeared, and which furnishes the characteristic, disgusting odor of these lesions. Heat, moisture, friction, perspiration, and neglect of the bath are fertile agents in their production in the axillæ, perineum, groins, the inner faces of the thighs, about the vulva, and elsewhere.

3. Papules may scale at apex or base, and the scaling become so significant a part of the process that the papular character of the lesion is almost disguised. In this way is produced the papulo-squamous syphiloderm. The scales are commonly scanty, desiccated, dirty gray in color, often attached, occasionally freely shed from the surface. Beneath them may be seen elevated papules having the so-called copper color, with the smooth, glazed surface of such lesions, or dull-red maculæ. Rarely the surface granulates.

PALMAR AND PLANTAR SYPHILODERMATA.—Syphilitic papules of the palmar and plantar surfaces are peculiar: (1) Because of the unusual thickness of the epidermis of the region affected; (2) because of the intermittent friction, contact, and exposure to which the organs are subjected. They may be early or late, transitory or peculiarly obstinate, and recurrent lesions. Careful inspection of the palms of the majority of patients exhibiting a copious macular exanthem will result in the detection of a few pea-sized discolored blotches in this region, which often are covered with a thin, slightly adherent scale. In greater approximation to the type of the average cutaneous papule, firm, circumscribed, dull-reddish, and distinctly elevated lesions, from the size of a large pinhead to that of a pea, are often seen in the same region. A variation from this type produces the dirty-whitish, corneous, epidermal masses embedded in the palms and soles like foreign bodies, and almost as readily separable. These are arrested forms of complete evolution of the syphilitic papule in the palms and soles. When progressing, unmodified by treatment, they become depressed and poorly defined in outline, coalesce so as to form circumscribed patches, from the size of a coin to that of an egg or larger, with newly developed outlying lesions. The next features are unquestionably impressed upon the patch by the traumatism and stretching of the infiltrated skin Scaling follows, centrally and at the periphery; fissures form in the lines of the furrows; ulcers develop, centrally situated, circular, oval, or stellate in outline. A purplish-floored ulcer is often seen here, its contour suggesting the fracture of a pane of glass. Recurrent and abortive attempts at reproduction of the palmar and plantar epithelium result in the formation of strata of ragged-edged epidermis, which irregularly fringe the deep losses of tissue. The entire palm or sole may be involved, and the process gradually sweep up to the wrist, instep, or ankle, and over the digits, affecting also the nails. The dorsal surfaces are occasionally involved, but always by extension from the palms or soles. Psoriasis limited to the palms and soles is of exceedingly rare occurrence; the specific lesions of this region are far more common, and are often accompanied by other unmistakable signs of syphilis with a history of infection. Squamous eczema is at times limited to the palms and soles, but, in the vast majority of all cases, affects the entire region, including the palmar faces of the digits, and is accompanied by itching. (See Plate LIV.)

THE PUSTULAR SYPHILODERM. — Pustules occur as early and late manifestations of syphilis, being, however, less frequently observed than the lesions just described. The purulent content may be sterile or contain the common pyogenic micro-organisms. The lesions are of the size of a pinhead to that of a bean, transitory or persistent, with mild or grave symptoms, and may originate as macules or papules, be isolated or grouped, scanty or abundant, and result in crusting, ulceration, and cicatrization. "Papulo-pustular," "pustulo-crustaceous," and similar terms are employed to indicate these mixed forms. Authors have also employed the phrases "acneform," "variola-form," "impetigo-form," "ecthymaform," etc., to designate the several varieties of the pustular syphilodermata. These terms are here purposely omitted, for the reason that the several diseases whose names are selected for comparative purposes are represented by lesions widely varying in the different stages of each disease, and exhibiting different features in different individuals. The phrases "syphilitic psoriasis," "syphilitic eczema," etc., are similarly discarded, as tending to contribute to the same confusion.

The Small, Acuminate, Pustular Syphilodermata.—The lesions of this class are of the size of a pinhead and larger, vivid or dull red, roundish, rapidly or slowly formed, and superficially seated, isolated, or wellnigh confluent pustules, which may be copiously developed in a general exanthem with syphilitic fever, or, more commonly, recognized in clusters about the regions where the pilo-sebaceous follicles are large and abundant. They may begin as macules or papules. The apex of each becomes yellowish-green as the pus forms, which may desiccate into minute crusts or may cover underlying ulcers of similar size. They assume at times circinate outlines. They are often seen on the scalp, face, neck, and trunk; rather less frequently on the extremities. Involution is often followed by rather persistent pigmentation; more rarely by minute atrophic scars.

The Large, Acuminate, Pustular Syphiloderm.—Yellowish-brown, conical pustules, of the size of a pea and larger, may develop slowly from the small lesions just described, or rapidly from maculo-papules. They are usually superficial in situation, become crusted at the apex, and, after the formation of the crust, may be depressed centrally Ulcers frequently form as the result of this process, the healing of which may leave small cicatrices. They form over the scalp, face, neck, shoulders, and extremities; and are usually the expression of either a graver form of syphilis or of a syphilis less judiciously managed than the lesions previously described

The Small, Flat, Pustular Syphiloderm.—This is a relatively frequent manifestation of syphilis, beginning by the development of circumscribed macules or maculopapules, which rapidly form flat, roundish pustules, the size of a pinhead and larger, superficial in situation. They are usually grouped, isolated, and at first not confluent; but their reddish and purplish areolæ become fused, and the whole is soon covered with a flattened, dirty-yellowish, and greenish crust, which commonly surpasses the limits of the patch. On the removal of the latter, a violaceous surface is seen, granulating, puriform, occasionally superficially eroded, possibly ulcerated. These lesions are often seen in and about the scalp, and about the lips, chin, beard, and trunk. In persons of weak constitution, and not properly treated, the face will occasionally be found almost completely covered by an irregularly crusted mask, formed in the manner described above, the pustulo-crustaceous lesions occasionally spreading in a serpiginous course, or forming the familiar rings, or segments of rings, seen in the grouped syphilodermata.

The Large, Flat Pustular Syphiloderm.—Pustules, the size of a bean and larger, deeply seated, or projected from the surface, may represent any of the forms described above, proceeding to full evolution, usually in cachectic subjects. They represent, also, the later periods of the so-called secondary stage of syphilis. Often they have dark red, deep, infiltrated bases with violaceous areolæ; and the pus finally desiccates into thick, bulky, greenish, or blackish crusts, firmly adherent to the edges of a foul-based, hemorrhagic, or pus-filled chamber beneath; or, after bursting, they leave open, sharply cut ulcers, with blood or pus freely formed from an exposed, eroded, sloughing surface. The ulcerative phase, with its crust, is indeed often the conspicuous feature of the process, the deep-seated pustular lesion which ushered in the mischief being thus speedily metamorphosed. These ulcers may be few or numerous, superficial or deep; and may be in outline circular, oval, semicircular, dumb-bell-shaped, etc. Their cicatrization commonly results in a typical syphilitic cicatrix.

RUPIA.—This term was at one time employed as the name of a distinct disease. It has long since lost any applicability to non-syphilitic disorders. Every rupia should to-day be recognized as syphilitic. Indeed, according to modern usage, the name merely describe certain peculiarities in the syphilitic crust. The explanation of its former temporary and unmerited elevation to the dignity of a disease supposed to have a separate entity is to be found in the fact that occasionally a patient will be extensively covered with rupioid crusts, who exhibits scarcely another symptom of syphilis.

The crusts thus named may be few and small, or large and generalized. First appear macules, then pustules, the contents of which desiccate into crusts of greenish, brownish, and blackish shades, covering and nicely fitted over underlying ulcers. The ulcer slowly spreads at the periphery, and its purulent and hemorrhagic secretions add by desiccation to the bulk of the crust. The additions are made beneath and laterally to the under surface and edges of the closely adjusted crust, which hence becomes a conical, stratified shell, usually with a slightly concave inferior surface, the whole often compared to an oyster shell. Each succeeding stratum of incrustation, from the conical apex of the crust to its base, represents, therefore, a somewhat larger ulcer and a somewhat more abundant secretion. There may be an outlying violaceous areola. The indolently spreading ulcers beneath correspond in size to the shells which cap them. They may be superficial or deep, but usually have a foul, purulent, or hemorrhagic floor, and punched out edges. Grave as is the condition of the patient who is extensively covered with the largest-sized rupioid lesions, the best of results may be anticipated under proper hygienic management and energetic treatment.

THE VESICULAR SYPHILODERM.—Vesicles are rarely the results of the syphilitic process in the skin. They usually point to an exudation more acute in type than that recognized in the indolently traversed cycle of syphilis. Occasionally miliary papules exhibit a vesicular apex containing a droplet of serum. Circinate and other groups of vesicles are described by French writers as of occurrence in this disease. Two explanations of the so-called vesicular lesions are at hand: first, the development of eczema, herpes, etc., in infected persons—phenomena not rarely observed by an expert; second, the occurrence of vesicular lesions provoked by extensively applied or internally ingested medicaments employed for the relief of the systemic disorder.

THE BULLOUS SYPHILODERM.—Discrete, roundish bullæ, from the size of a pea to that of a small egg, appear simultaneously or in crops upon the syphilitic skin, in consequence of a more or less circumscribed elevation of some portion of the epidermis by accumulation of a clear lactescent serum, pus, or blood. The contents usually desiccate into bulky, adhesive, stratified, greenish or dark colored crusts, which may cover granular, eroded, or ulcerative surfaces. Often they are surrounded by a violaceous halo. The ulcer, after removal of the crust, may spread in depth or area, or cicatrize; this according to the vigor of the patient and the treatment pursued. Lesions of this sort are rather more often recognized upon the extremities than elsewhere, in consequence of the greater distance of the latter from the centres of circulation. They are more often encountered in late

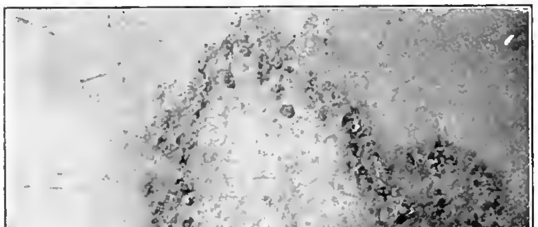

FIG. 4587.—Serpiginous Tuberculo-ulcerative Lesions of the Skin of the Back.

periods of the disease, and in cachectic subjects. They are for these reasons most often seen in the tender skin of the infant who is the victim of hereditary syphilis.

It should not be forgotten, when making a diagnosis of the bullous syphiloderm, that the iodide of potassium, in exceptional cases, is capable of producing such lesions in typical aspect when administered to the syphilitic as well as to the non-infected patient. American observers chiefly have called attention to this important fact, among them Drs. O'Reilly, Graham, Morrow, and the author.

THE TUBERCULAR SYPHILODERM.—Hyperplastic evolution of the papule, besides producing the aberrations from type already described, may also result in the formation of definitely circumscribed, deeply-seated, single or multiple, bright-reddish or livid, solid, cutaneous or more commonly subcutaneous, lesions, from the size of a pea to that of a small egg, known as tubercles. These are usually late syphilitic symptoms, which, in consequence of difference of involution, are divided into two classes.—the resolutive and the ulcerative.

The *resolutive tubercular syphilide* is characterized by slow evolution without marked subjective symptoms, disappearance after absorption of the plastic infiltration commonly involving the entire thickness of the derma, and the production, without previous ulceration, of an indelible scar. The lesions begin as superficial, reddish, and roundish gummatous nodules, the size of a pinhead, which, as they attain the larger dimensions named above, become flatter, smoother, more lustrous, and more deeply tinted. They are largely facial or cervical in situation, but may also spread over the trunk and extremities. They are often free from scales, except when seated upon the palms or soles, in which situations they may be covered with thick corneous plates beyond the borders of which can be recognized a violaceous halo. These lesions may be generally disseminated, or grouped in distinctly circumscribed patches, either circular in outline or exhibiting some modification of the latter (*e.g.*, the reniform, horseshoe-shaped figure, etc.). The former are the earlier; the latter the later, of occurrence.

When facial in situation, the tubercles may spread in a fan-shaped area over the forehead, or extend over the bridge of the nose to the cheeks, assuming the figure of a butterfly. The thinned, atrophic centre and elevated rim of the patch may then be significant.

An exaggerated grade of confluence and proliferation of these tubercles results in the hypertrophic, leontiasic, or vegetative syphiloderm. In these instances the nose, the chin, the ear, or some other part presents an enormous increase in bulk, with definitely distinguished lobules separated by furrows, the picture presented strongly resembling the elephantiasic condition. Again, a voluminous verrucous growth may spring from some portion of the scalp, and even in the end encroach upon a large part of that region, the warty mass freely projecting comb-like masses from the surface, smeared often with a puriform and offensive secretion (frambœsia syphilitica, papilloma syphilitica, etc.).

The *ulcerative tubercular* (*tuberculo-ulcerative*) *syphiloderm* is a somewhat later manifestation of the disease, or one which, developing as it does rarely within a few months after the evolution of the chancre, occurs in neglected, untreated, cachectic, or so-called "galloping," cases. Here also the lesions appear upon the face, trunk, and extremities, with the general characteristics already described, but more commonly in definite groups. Instead of undergoing, however, the atrophic changes observed in the resolutive form, a portion, rarely all, of the tubercles forming the patch, soften or become covered with a greenish or blackish crust from desiccation of the ichorous or sanguinolent liquid furnished by the breaking down of the gumma, beneath which an ulcer forms somewhat larger in size than the lesions from which it sprang. In this way the face may display over the chin, forehead, or cheeks a dense tumefaction composed of a group of closely agglomerated, livid papules, ulcers, and crusts, the size of a pea, or a distinctly outlined ring of such lesions disintegrating at the periphery and surrounding an atrophic, cicatricial, or even ulcerated central area. Gangrene and phagedena very rarely complicate these destructive processes. The ulcers which form are

of a typical syphilitic aspect, with pultaceous floor, steep, "clean-cut" edges, ichorous secretion, and serpiginous tendencies.

Mixed forms of commingled resolutive and ulcerative tubercles are not of rare occurrence. The following are

FIG. 4588.—Enlarged Portrait of Group of Lesions shown in Fig. 4587; showing Peripheral Extension by Multiple Circumscribed Ulcers.

common clinical pictures: A patient, from five to ten years after infection, has the forehead, nose, and cheeks fully covered with numerous, firm, smooth, shining nodules, the size of a pea, vivid and dull red in hue, occupying an infiltrated integument of the same general color. Some of the tubercles are slightly crust-capped, others are irregularly excavated as if wasting at such points. Between them are distinctly defined, atrophic, non-pigmented depressions from the size of a large pinhead to that of a pea resembling youngish scars. These are spread with some regularity between young and mature tubercles even at the scalp border and among the hairs over the tip of the nose and well over the cheeks. Uneven and verrucous patches may indeed occupy distant portions of the scalp where hairs have fallen from an atrophic area. Sometimes they undergo colloid degeneration. Attention is particularly directed to this complexus of nodules, crusts, atrophic discs, minute ulcers, and scanty pustules when occurring in this region, as it is a feature very rarely seen in any other disease than syphilis.

In most of these cases the changes wrought in the course of time after the employment of an appropriate therapy are marvellous. The violaceous tint disappears; the scars, if any have resulted, are transformed into thin superficial uncolored or dead-whitish inconspicuous blemishes; the natural fat of the panniculus adiposus is restored; and, even in middle life, after the fullest grade of evolution described above has been reached in the face of a woman, a fair degree of comeliness is restored.

Lupus vulgaris is distinguished from this condition by its onset at an earlier period of life, its far narrower limitations, its greater asymmetry, its profounder and more disfiguring scars, and its much more indolent career. The tubercles of lepra producing the characteristic leontiasic aspect of the face are far more chronic in evolution, more deeply pigmented and "varnished," less often ulcerated, crusted, and commingled with scars. The pearly, milium-like nodules of epithelioma are quite unlike the tinted tubercles of syphilis, are never so numerous, and the smooth-glazed, bright red, and scantily secreting floor of the epitheliomatous (rodent) ulcer never suggests the foul excavations of syphilis. Psoriasis is always scaly, never ulcerative in type, never crusted nor pustular. The most difficult cases for differential diagnosis are those of hypertrophic acne of the nose, with gaping orifices of sebaceous ducts whence comedo plugs may have been expressed, interspersed between dull reddish acne papules. Here the history of the case, the absence of scalp-lesions, the stricter limitation of the patch to the tip and alæ of the nose, the absence of a distinct ulcer, and the conspicuously smaller size of the scar-like depressions, usually furnish a clew to the distinction sought to be established.

The blastomycotic patch is almost invariably distinguished by its characteristic encircling border or wall, on the sound side of the integument sloping gradually to the level beneath, studded with exceedingly minute pin-

FIG. 4589.—Tubercular Syphiloderm of the Shoulders, showing Scars and Pigmentation.

point-sized abscesses, in the contents of which can readily be distinguished the double contoured organism with its lucent lenticular space within.

THE GUMMATOUS SYPHILODERM.—Single and multiple, isolated or massed nodules, from the size of a pea to that of an egg, or larger, originating simultaneously, but commonly invading the skin as they develop, occur in late, rarely in early, periods of syphilis, and are termed gummata in consequence of the gummy material they furnish when disintegrating. They are rarely numerous, often not more than from two to six affecting a single patient. As an exceptional fact, hundreds may be seen covering different regions of the body. They are peculiar to syphilis; in other words, they do not pursue, in the course of other affections, the same classical cycle of evolution and involution. Yet they are really syphilitic tumors, allied, on the one hand, to the hyperplastic process which produces the papule and tubercle, and, on the other, to the histological type of tumors in general. Pathologists have some ground for believing that the so-called gummous material of this lesion is to be recognized in the nodules that glue the iris to the capsule of the lens, and even in the neoplasm that constitutes the mass of the initial sclerosis.

FIG. 4590.—Gummatous Ulcer Simulating "Rodent Ulcer," near the Root of the Nose.

After development, gummata may for a long period of time be perceptible beneath the skin as smooth, circumscribed, insensitive, firm nodules, undergoing no change. Later, they become slightly painful; there is passive hyperæmia of the overlying skin; attachment between the skin and the tumor is effected; then follow, usually, fluctuation and evacuation (spontaneously or by surgical interference) of inspissated blood and pus, or of the contents of a true, circumscribed abscess. The gummatous mass constituting the tissue, bathed in pus and blood, is slowly or rapidly removed by this process, in the course of which is formed the gummatous ulcer. This has the circular outline, precipitous edge, sloughy floor, foul secretion, livid halo, and phagedenic tendencies already described as characteristic of the syphilitic ulcer in general, with this special added feature, that it is particularly deep. Its floor rests on subcutaneous tissues. It may involve fasciæ, periosteum, muscles, large vessels, bursæ, nerves, bones, tendons, and other important tissues. Its walls, carefully inspected, often exhibit the sharp and resisting edge of a dense aponeurosis, the glistening white border of a tendon, or the firm periosteum sheathing an osseous plate.

Occasionally gummata are lodged in, rather than beneath the skin, the firm, movable mass being then readily defined by palpation. Whether superficial or deep in situation, they may undergo complete resolution. When disintegrating by ulceration, they may go on to produce those extensive and formidable losses of tissue, complicated with erysipelas, pyæmia, etc., in the subjects of cachexia and alcoholism, which make syphilis, in some of its manifestations, a veritable scourge. Though occasionally numerous, not more than from six to eight are usually to be recognized in the person of a single patient. They are most frequently developed upon the lateral surfaces of the legs, and, next, proportionally after these, over other parts of the extremities, the face, scrotum, buttocks, neck, and the breasts of women. The importance of their recognition in the last-named situation, when the question of cancerous and other malignant tumors of this organ is presented for consideration, can scarcely be overestimated. The author has seen a gumma the size of a turkey's egg in the breast undergo complete involution under specific medication only.

The elephantiasic aspect of the face and legs of certain patients who are afflicted with extensive gummatous tumors and infiltrations of the cutaneous and subcutaneous tissue is a matter of great moment for the diagnostician. In almost every community there is some such patient, with a striking deformity, the nature of whose malady has been altogether unknown for years. In such cases there is often an obscure history, which, perhaps, the expert alone has been able correctly to interpret. The patient has been supposed to be the victim of "elephantiasis." The nose, lips, cheeks, and chin are possibly densely thickened, distorted, empurpled, and irregularly ridged and seamed with nodules, scars, and ulcers; or the leg is in the pachydermatous condition seen in the "Madura foot" and other diseases. It is a large, unwieldy organ, ridged, of cartilaginous hardness, furrowed, and covered with an integument looking like the

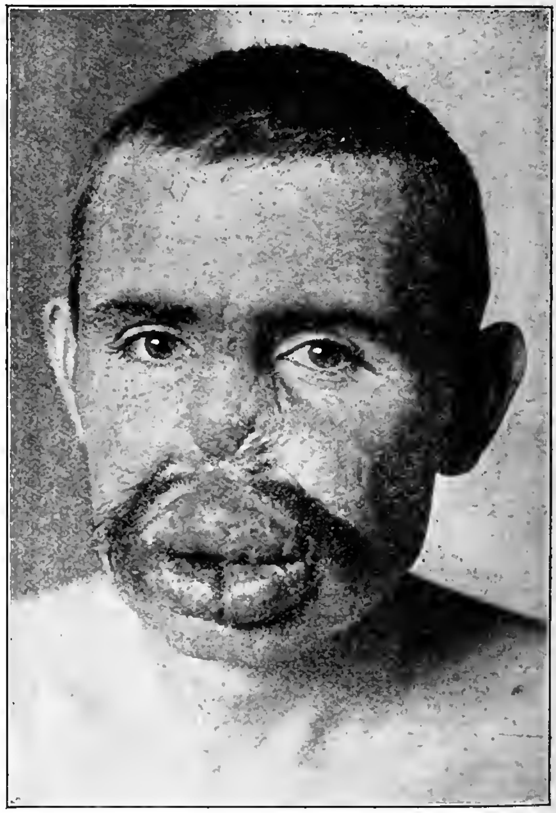

FIG. 4591.—Gummatous Changes in the Face Simulating Lupus Vulgaris, Resulting in Occlusion of the Nares.

bark of a tree. Careful inspection, however, always reveals in this mass the typical cicatrices of ancient gummatous ulcers, and the traces of new and old nodules buried in the hypertrophied and œdematous mass. Here, as in so many other of its formidable aspects, syphilis reveals its amenability to proper management. The changes that can be wrought by treatment in these apparently desperate cases are in a high degree satisfactory.

The Serpiginous Syphiloderm.—Though not distinguished by the name of an elementary lesion the preponderance of which might justify such a position, this syphiloderm has an individuality requiring separate consideration.

In its superficial forms the serpiginous syphiloderm is preceded by the appearance of small, pointed or flat syphilitic pustules, which form a circular or partially circular group of lesions in discs of the size of an egg and larger. These discs are soon covered with a yellowish, greenish, or blackish crust, which gradually clears from the centre, leaving there a granulating or smooth, reddish or normally tinted, atrophic or only superficially altered integument, surrounded by an entire or broken ring of attached crusts, beyond which is a livid halo. Underneath this latter is a superficial, centrifugally spreading ulcer, uniformly annular in contour, or here and there broken by bridges and islands of unaltered skin. Often this annular ulcer is seen to be composed of roundish excavations, the size of a pea and larger, arranged circle-wise, with confluent crusts. In other cases the crust is scarcely more than a narrow ring, no broader than the smallest penknife blade, which, as it spreads centrifugally, leaves cutaneous areas of former invasion the size of the palm and larger, pinkish-red or slightly pigmented in color, at times decidedly cicatriform, at other times texturally unaltered. In this way an entire buttock or limb, or the face, may be progressively involved.

The deep serpiginous syphiloderm generally spreads from a gumma or other late lesion of syphilis. A deep ulcer results, which attacks the subcutaneous tissues. The centre is soon represented by a tender or firm scar; the advancing edge by a thick, greenish or blackish, adherent crust, covering a deeply cut circular exulceration with punched-out walls and foul secretion. The dull, purplish areola of all similar lesions is visible at the periphery beyond its advancing edge. Its progress over the skin is decidedly more serpiginous than in the direction of the radii of a circle. Here and there a kidney-shaped or horseshoe-shaped edge exhibits a deeper excavation, or a more tenacious, bulkier, and darker crust. In yet another part of the same disc the ring may be represented by a partially cicatrized border, or by a wide bridge of unaffected skin. This is a late, exceedingly obstinate, and intractable form of syphilis, leaving generally a deforming scar. It is to be distinguished from lupus vulgaris (which is more often seen on the face) by its definite outline, its deep pustular, rather than nodular, elementary lesions, its sharply cut ulcerations, but, above all, by its relatively much more rapid progress.

Malignant Syphilodermata.—Syphilitic cutaneous and subcutaneous lesions are at times malignant in type, and then commonly precocious in occurrence and acute in course. They are described by Bazin and other French authors as "malignant precocious syphilides." The intensity and violence of the symptoms in these cases is in general due to the occurrence of the disease in cachectic subjects, those who are debilitated by age or previous or concurrent diseases, those deprived of the essentials of healthy living, viz., wholesome food and drink, hygienic environment, freedom from mental anxiety, and a proper adjustment of labor to bodily vigor.

In patients of this class the chancre is scarcely cicatrized before symptoms threatening malignancy appear. They are divided by most authorities into (*a*) the puro vesicular syphiloderm; (*b*) the tuberculo-ulcerative syphiloderm; (*c*) the gangrenous tuberculo-ulcerative syphiloderm. These names are mainly groups of symptom phrases, the lesions themselves exhibiting a wide variation indicated by both mild and grave characters.

The milder forms are really rupioid lesions following isolated or grouped pustules, which are rapidly followed by ulcers, thickly covered with laminated crusts. In certain cases, when the disease has progressed for long periods of time, the resulting keloid like scars are both extensive and disfiguring. (See Plate LV.) In a more accentuated form the malignancy of the outbreak is indicated by the development of blebs or lenticular tubercles, which hasten to break down into ulcers of characteristic syphilitic edge, secretion, floor, base, and areola, which attack the face, trunk, hands, or extremities. The graver

Fig. 4592.—Extensive Gummatous Ulceration of the Left Arm, with Production of Keloid in Cicatrized Portions.

forms are tubercular, ulcerative, and gangrenous. A group of nodules in or beneath the skin surrounds itself with significant purpuric points, supposed to indicate an endarteritis of the peripheral vascular elements. The whole rapidly or slowly becomes gangrenous, showing a dry, blackish eschar, which spreads at the periphery, and insidiously, as it encroaches upon the sound tissues in the vicinity. Sometimes a line of demarcation is formed, not between the gangrenous mass and the sound skin, but between the former and a thickened empurpled zone which surrounds it. When the slough is removed, a conical crateriform ulcer is exposed, having a fetid secretion, a sloughy floor, and markedly everted edges. The destructive process may progress till fatal results are produced, the patient succumbing to fever or marasmus and adynamia. But this is rare. Under the best treatment repair sets in, granulation is followed by cicatrization, and there is apparently complete restoration of the general health.

Cutaneous lesions and symptoms other than the forms described above are neither numerous nor important, but have been described by authors. Bronson, of New York, has described an erythanthema syphiliticum in which vesico-pustular and other lesions were grouped upon an erythematous base. Hemorrhagic effusions within the skin occur chiefly in patients who are the subjects of hæmophilia, and who have also contracted syphilis; in children afflicted with hereditary syphilis; in patients with paraplegia resulting from syphilitic involvement of the cord (purpura of the lower extremities); and as an accident of a number of secondary and tertiary lesions. The author has seen two such cases occurring in syphilitic disease of the cord. It should be remembered that the iodide of potassium, when administered for the relief of syphilis, may produce purpuric spots, especially over the lower extremities.

Lastly, eczema, psoriasis, the animal and vegetable parasitic affections of the skin, pruritus, and the various dermatites, all the forms of acne due to the ingestion of the iodic compounds, and other cutaneous disorders, affect the syphilitic as well as the non-syphilitic patient. Each of them exhibits its special peculiarities, apparently not at all or very slightly modified by the syphilitic infection, and is recognized in its identity as distinct from the manifestations of syphilis without great difficulty on the part of the diagnostician. This recognition is a matter often of the highest moment, as the anxiety and dread occasioned in many patients by the discovery of these intercurrent affections (to which the mass of mankind is subject) are out of all proportion to the real import of the symptoms presented in such cases.

Treatment of the Syphilodermata.—The internal treatment of the syphilodermata is that of syphilis in general, including the use of mercury, the iodide and other salts of potassium, iron, cod-liver oil, and a nutritive regimen.

Many of the lesions, however, require local treatment. The salves which are most effectively used with this end in view contain one of the salts of mercury. Among these may be named the ammonio-chloride, in the strength of from five grains to two drachms to the ounce (0.33 to 32.0); the red oxide, in the strength of from five to ten grains (0.33–0.66) to the same quantity; the ten or twenty per cent. oleate of mercury; the mild chloride, in the strength of from ten to thirty grains (0.66–2.0); mercurial ointment, in the strength of from half a drachm to a drachm (2.0–4.0) to the ounce; and the ointment of the nitrate of mercury in nearly the same strength. The bases of these salves may be vaseline, cold cream, lanolin, or simple cerate, a drachm (4.0) or more of glycerin being added to the ounce (32.0) of each when requisite to produce softness in the mass. Vaseline is preferably employed as a basis for salves to be applied over the scalp and hairy parts.

The tars also are often employed with advantage, including the oleum cadini and the oleum rusci (rectified or crude), in the strength of from half a drachm to a drachm to the ounce (2.0–4.0 to 32.0) of basis, adding an equal quantity of finely levigated prepared chalk to obtund the sharpness of the tar. These are excellent applications to palmar and plantar syphilodermata, when preceded by maceration of the affected surfaces for several minutes in water as hot as can be tolerated. Often the thick epidermal scales of these regions are best removed at the time of these macerations by the aid of a shampoo prepared by adding an ounce of glycerin to two or more ounces of the tinctura saponis viridis of the Pharmacopœia. After the shampooing with hot water, the hands or feet are dried, the salve well rubbed in, and gloves are drawn over the hands, or stockings over the feet. Other ingredients are often incorporated with such salves with excellent effect. Among them may be named salicylic acid, ten to twenty grains to the ounce (0.66–1.33 to 32.0); chrysarobin, pyrogallol, and ichthyol, in the same strength; zinc oxide and the subnitrate of bismuth, half a drachm to a drachm to the ounce (2.0–4.0 to 32.0); and the oleate of lead, in the form best known as Hebra's unguentum diachyli albi.

Powders occupy a most important place in the local management of the syphilodermata, more particularly those that are ulcerative in type. Among them may be named europhen, iodoform, iodol, aristol, hydronaphtol (one part to fifty of fuller's earth), boric and salicylic acids, calomel, starch, camphor, and lycopodium. Many of these are advantageously employed over such moist lesions as condylomata after they have been washed in a lotion of chlorinated soda or carbolic acid, so as to be not only deodorized but thoroughly cleansed.

Lotions of the kind just suggested are useful in the management of a number of the secreting syphilodermata. Others are compounded with the corrosive sublimate, one-half to one grain to the ounce (0.33–0.66 to 32.0) of bay rum, cologne water, or the rectified spirit of wine. Lotions containing tar, salicylic acid, carbolic acid, and boric acid (often in saturated solution) meet the indications of many cases.

For the purpose of stimulating or otherwise dressing mucous patches and indolent ulcers, solutions of the nitrate of silver, five grains to a drachm to the ounce (0.33–4.0 to 32.0), or crayons of the solid salt may be used; or even the strong caustic solutions, *e.g.*, of the hydrate of potassium twenty to sixty grains to the ounce (1.33–4.0 to 32.0), or of nitric acid. Solutions of corrosive sublimate in tincture of benzoin, or of myrrh, one to two grains to the ounce (0.066–0.033 to 32.0); benzol, creosote, and solutions of the permanganate of potassium and resorcin, one to five per cent., are also useful in many cases; the first two for destructive effects, the last as antiseptic dressings.

Many of the syphilodermata are effectively treated by the modern methods of radiotherapy (exposure to the *x*-ray). The duration and frequency of the exposures, together with the precautions needed to avoid the serious consequences of improper use of this effective and often proportionately dangerous agent, are governed by the rules formulated in experience acquired by treatment of non-syphilitic cutaneous affections by the same method. We have reserved the application of the rays to obstinate chronic engorgements of the skin, such as are occasionally recognized in the palmar and plantar syphilodermata; and to some of the persistent mucous and scaling patches of the lining membrane of the mouth.

The principles on which should be based the local treatment of the syphilodermata are those recognized in all similar non-specific affections of the skin. Of chief importance is the treatment of the disease itself, whether by internal medication, inunction, fumigation, or hypodermatic injection. To this, in most cases, the local treatment may be added with marked advantage. The scalp, hands, and feet may be often shampooed, and subsequently dressed with a salve or lotion. Pustules are to be opened, crusts removed, and small or large ulcerated surfaces cleansed, cauterized, or stimulated, and antiseptically dressed. Soap and water are as imperatively required for the syphilitic as for the non-syphilitic skin. Frequent applications of water as hot as can be tolerated are often required for the relief of pain, and the surgeon's knife is needed for opening softened gummata. In extensive syphilitic ulcerations an exceedingly valuable resource is the use of the continuous hot-water bath as employed in Vienna, the patient, if his ulcers can be in this way immersed in the water, remaining in it for hours, the bath being kept as hot as is grateful to the surface of the immersed skin. The bath is left only on occasions requiring evacuation of the contents of the bladder or of the rectum, or in order to secure sleep. Lastly, the mercurial, rubber, lead, and other surgical plasters, borated cotton, antiseptic lint, and wool (medicated with the mercuric iodide), prepared oakum, fuller's earth, and the other articles needed to make the dressings of modern surgery, are never more useful than in the management of multiple or extensive syphilitic ulcers.

Affections of the Hair, Hair Follicles, and Hairy Regions of the Skin.—A common manifestation of syphilis is a loss of hair, in excess of the physiological defluvium capillitii, resulting in alopecia. This

LATE SYPHILITIC ERUPTION (ULCERS) PRECEDED BY BULLAE, IN A CACHECTIC SUBJECT.

PHOTOGRAPH TAKEN A FEW DAYS BEFORE THE DEATH OF THE PATIENT.

(From the Collection of Photographs of Skin Diseases belonging to Dr. John A. Fordyce, of New York.)

may be an early or a late symptom, rapidly or slowly occurring, scarcely perceptible or greatly deforming, and transitory or resulting in permanent baldness.

The earliest form of alopecia may occur without local subjective or objective sensations, the symptoms being often limited to the loss of hair. It may again be accompanied by macular, pustular, papular, ulcerative, or crusted lesions of the regions affected. It may appear as early as the date of the first syphiloderm, and, indeed, may be the first significant or even the chief feature of general syphilis. In other cases it is conspicuous only after the third or later month of infection. It may affect any hairy region of the body, but is more commonly noticed on the scalp, beard, mustache, eyebrows, and lashes. Upon the scalp, it is probably much more common of occurrence than of observation, since it is often first recognized in men only after the hair is cut short.

The hair may appear to be merely thinned in syphilitic alopecia, when the pilary loss is actually conformed to type. The close-shaven head of the syphilitic, affected with the early form of alopecia, presents almost always the same appearance. The scalp is then seen to be covered with irregularly circular areas of baldness, symmetrically arranged as regards the two halves of the body, these areas varying in size from a split pea to a small coin. There is asymmetry, however, in the disposition of individual patches. The scalp thus affected may be apparently sound, or dry and lustreless, or, as described above, the seat of a syphilitic exanthem. When the hair is long, as in women, the striking disfigurement visible on the shaven scalp is scarcely apparent; in men whose hair has been cut moderately short the effect is that of a characteristic patchy irregularity, in which it is clear that the temple and occiput are as much affected as the vertex. The eyebrows, eyelashes, and mustache may be merely thinned, or suffer a loss in patches. The shaven beard may present an appearance nowise distinguishable from the condition of the same region when affected with alopecia areata.

The late forms of syphilitic alopecia are always due to destructive lesions of the cutaneous region covered with hairs; and the alopecia is hence usually the less important feature of the disease. Thus deep pustular, gummatous, ulcerative, and other like changes in the scalp are usually followed by an asymmetrical loss of hair, often limited to a single patch, where, after cicatrization, the resulting alopecia is remediless.

The early form of alopecia is unquestionably chiefly due to defective nutrition of the hairs in the hair follicles, and, as alopecia areata is probably due to the same immediate cause (the remote cause being essentially different), it follows that the shaven scalp presents almost the same appearance in two selected cases of the two diseases. The bulbs of the fallen hairs are seen under the microscope to be distorted and misshapen in early syphilitic alopecia, and the hairs themselves are usually dry and lustreless. The pathology of the late forms of alopecia in syphilis is that of the syphilitic process to be studied in the tissues generally. Usually a degenerating gummatous infiltration eventually encroaches upon and destroys the hair follicle. Syphilitic alopecia is to be distinguished from all physiological losses of hair by its sudden occurrence in persons of the age in which syphilis is most commonly encountered, its asymmetry, and its involvement of the temples and occiput equally with the vertex. A history of infection can usually be obtained, and other symptoms can often be discovered. Seborrhœa capitis, or alopecia furfuracea, is distinguished by its fatty or dry scales, and its failure to remove the hairs in distinct areas. The patches of alopecia areata strongly resemble those of early syphilitic baldness in the shaven head; the loss, however, in the former disease is more sudden, and recovery is marked by the appearance of whitish or grayish downy hairs, which is not often the case in restoration after syphilitic alopecia. The internal treatment is largely that of the secondary symptoms of the disease. The local treatment should consist of daily shampooings with hot water and the Sarg fluid soap; or, when mere stimulation is required, by the aid of the tincture of green soap. After such shampooing the scalp may be anointed with scented lanolin or vaseline, or with an oleaginous lotion made by adding two drachms (8.0) each of the oil of sweet almonds and glycerin to an ounce (32.0) each of the spirit of rosemary and alcohol, and two ounces (64.0) of cologne water.

Affections of the Nails, Matrix and Bed of the Nails, and Adjacent Parts.—The term onychia is applied to the changes which are first apparent in the nail; and paronychia to those which only secondarily affect the nail and primarily the matrix, nail-bed, or cutaneous folds by which the nail substance is surrounded. It is probable that the distinction is purely artificial, both forms being preceded by alterations of tissue exterior to the nail substance proper. These appendages of the skin are frequently affected in syphilis, both during the secondary and during the tertiary stages, and the resulting lesions may be transitory or persistent, and mild or grave in character. The course of these changes is usually chronic.

In the most frequent form of onychia (*onyxis craquelée*—dry or friable form) a portion or the whole of one or several of the nails may become dry, lustreless, grayish-yellow in color, friable, rugous, irregularly thickened, traversed by furrows in one or more directions, or singularly disfigured by numerous minute pockets, from which the crumbling nail substance has fallen or been removed by washing and scrubbing. The nails are usually tilted up at the free border and separated from their beds. Careful examination will often reveal a ridge of thickened epidermis at the sides or attached border of the nail, which may be normal in appearance or dull purplish in color and scaling; or, on pressure, a few drops of thin, ill-conditioned pus may escape from beneath it. This form is said to be more common in women. Under treatment these phenomena may disappear, and the distorted nail be pushed forward and replaced by a healthy new one. In other cases one or several of the nails are insidiously loosened from bed, matrix, or nail-fold, and are shed without the occurrence of any appreciable change in the surrounding parts, precisely as the hairs fall in many cases of syphilitic alopecia. Sometimes, even when attached at its border, the nail is seen to be completely separated over its entire area from the bed beneath. When the nail, on the other hand, is affected with an onychauxis, it may increase to three or four times its normal bulk, a condition described by some writers as hypertrophic onychia.

Paronychia may affect the whole or a part of the nail, and be dry or ulcerative in type. In the former case a dull-purplish ridge of cutaneous tissue, in the vicinity of the nail-fold and including it, becomes indolently thickened, scaling, and fissured. Superficial ulceration may follow, with purulent or hemorrhagic secretion and crust formation, the ulcer spreading slightly beneath the nail at one point, the substance of that organ having already exhibited the changes due to impaired innervation. The characteristic feature of this complication is a finger with its distal phalanx having a bulbous appearance, its partially altered, dirty-looking nail tilted upward or to one side, and a dry, scaling, or indolently granulating surface exhibited in the exposed part of the bed.

Ulcerative paronychia is characterized by a shallow or deep ulceration extending at the central or lateral parts of the nail-fold, matrix, or bed, bathed with a sanguinolent, thin, or ill-conditioned pus. It may begin with the dry lesions described above, or with the development of marginally seated papules or pustules. The nail may, as a result, be in lateral deviation from the axis of the phalanx, or partially or wholly loosened from its attachments. In this state it may present any of the changes seen in syphilitic onychia. The nail-bed, when thus exposed, is usually tumid, covered with a thin, puriform secretion, granulating, or the seat of an irregular, firm, and whitish, epithelial investment. Thin layers of new nail substance speedily form over this surface if proper treatment be instituted; and, even in the cases in which a distorted nail at first covers the bulbous phalanx and its purplish, tumid nail-fold, the restoration is eventually complete. In some cases the ulcer first forms beneath a crust under the free edge of the nail, and thence, when not properly managed, spreads irregularly over the matrix, the nail becoming loose and undergoing the changes already described. Care should be taken in the diagnosis of such cases to exclude trichophytosis unguium (where the parasite is recognizable under the microscope); eczema and psoriasis (in which there is no history of syphilis and none of its other symptoms); digital chancres (in which the nails are not chiefly involved); and ordinary forms of paronychia (which commonly spare the nail-bed and matrix).

The treatment is largely internal; locally the white precipitate salve [one scruple to the ounce (1.33 to 32.0)] may be applied on rags. Ulcers may be dressed with pencillings of the nitrate of silver, followed with iodoform or iodol in powder.

The Relations of the Syphilodermata to the Process of Systemic Intoxication and to the Accidents of Environment.—The view was once generally held, and is still largely entertained, that the several eruptions observed in the course of evolution of syphilis are due solely to the constitutional malady. This position, viewed in the light of modern science, is seen to be untenable. The eruptions minutely described and definitely catalogued in the treatises upon this subject can, without difficulty, be assigned etiologically to several categories.

In the first are grouped syphilodermata due solely, so far as can be ascertained by our present methods, to the influence of the toxin of the disease. These eruptions constitute probably the smaller number of all with which the physician needs to be familiar.

In a second category are to be recognized the syphilodermata due wholly to externally operating causes, the accidents of environment. Some eruptions should be here included, in which manifestly the pyogenic staphylococci are the efficient factors in the production of the lesions, some of them resulting from inoculation, others from auto-inoculation. It is quite noticeable of the pustular syphilodermata that they are nowhere seen so abundantly and in such typical expression as among the filthy, the impoverished, and the neglected. They are decidedly among the rarer complications of the evolution of the disease among the cleanly, the well fed, and the comfortably clad. Specific treatment being for the time abandoned, the pustular syphilodermata as a rule respond rapidly to the treatment indicated by the existence of such lesions, viz., bathing, disinfection, asepsis, proper clothing, and shelter of the body. Some of the pustulo-crustaceous and bullous lesions acknowledge similar causes. It is an error to dissociate syphilis in all cases from the category of the filth-diseases. The worst varieties of the malady, without any question, are to be found in the lowest class of patients in the out-departments of public charities, where attacks are daily made upon the unwashed skin by micro-organisms, animal and vegetable parasites, the "flora dermatologica" of Unna, and the finger-nails of the sufferers.

In a third class are to be named the eruptive phenomena, due without question to the operation of an internal cause, but brought into existence, or encouraged, or precipitated, by externally operating accidents. This includes an enormous number of all the syphilodermata, and there are few that may not acknowledge influences of the sort to which attention is here directed. The mouth of the tobacco-chewer and smoker is often freed from mucous patches when relieved of the irritation thus aroused; the anus of the infant is no longer surrounded by a group of condylomata when its surface is properly cleansed and disinfected; the palmar plaques of the toiler with material or tool cease to ulcerate and begin to heal when labor is suspended, or the hands, when thus engaged, are protected from injurious contacts.

In a fourth class are to be placed a small number of supposed syphilodermata, due to causes operating internally, and to be attributed only in part to the infective process. Here should be described all the medicamentous eruptions, due to the iodine compounds administered for relief of the disease, chiefly the acneiform lesions (acne artificialis, acne varioliformis). With these should be enumerated eruptions of the class represented by the pigmentary syphiloderm which refuses to succumb to the action of the remedies commonly effective in syphilis, and which is in reality a pigmentary disorder only very indirectly associated with the toxic condition of the system.

In a fifth class are represented a number of the cutaneous pictures of syphilis, due to the commingling of syphilodermata with simpler dermatoses. Chief among these is the combination of syphilis and seborrhœa seen so often about the nose, the brow, and over the scalp of the subjects of the two disorders.

The Behavior of the Syphilodermata in the Presence of Other Infective Processes.—The knowledge had respecting the relation of syphilis to other diseases was of the vaguest character prior to the date of an exact appreciation of the etiological importance of micro-organisms in disease. The mutual antagonisms of the latter in several of the infective processes are made apparent in many of the morbid conditions presented in syphilis. Erysipelas may affect the skin which is the seat of syphilodermata, but then the result, far from suggesting a complexus of two disorders with a confused picture of each, is a typical erysipelas having an issue which leaves the skin, after relief of the later infection, free from the lesions first occupying the ground. Similarly, in observation of a series of cases of typhoid fever occurring at the moment of an abundant eruption of syphilodermata of an early type, the cutaneous symptoms wholly disappear with all other traces of syphilis, only to return, usually in milder expression, after the conclusion of weeks or months of illness and protracted convalescence, when the bodily weight is again nearly approaching its normal standard.

Syphiloma of the Subcutaneous Glands (Gummatous involvement of the lymphatics, so-called "tertiary bubo").—In those periods of syphilis, when gummatous material is deposited in any of the bodily tissues, the subcutaneous glands may suffer. This complication of the disease is more common than is generally supposed, and, when the glands of the neck are involved, presents a condition which is often mistaken for tuberculosis.

The subjects of the disease are not always in what has been termed the "late" stages of the disease. They are often the recently infected, even within a few months of the date of that accident, and, as a rule, are of the type formerly described as strumous. They are usually individuals of weak constitution, under normal weight, and poorly nourished, or severely taxed in daily toil. The glands are recognized as round and oval, dense and at times elastic swellings, involving one or a group of several glands ("pleiades" of French writers), which may pursue a gradual course terminating in disintegration, or undergo resorption of the deposit in any stage of development. The glands are at first in a purely irritative condition, thus probably resenting the entrance of either bacilli or toxins of the same in their meshes; later, there is a well-marked cell proliferation with degeneration of the central pulp of the gland, pus formation, and exit of the same, either spontaneously or by means of surgical interference; in other subjects caseation results, the cell proliferation decreases *pari passu* with increase of the intercellular tissue, and fatty metamorphosis eventually takes place.

The glands most frequently involved are, first, those of the neck (submaxillary, infraclavicular); next, those of the inguinal regions; lastly, the axillary, cubital, and popliteal.

The tumors vary in size from small nuts to large eggs, are both painful and tender, and soften when about to break down at or about the central point of the mass. They are exceedingly indolent, and even when converted into an abscess have little or no tendency to burst, but retain for weeks at a time, even longer, their pulpy and ill-conditioned contents. They are at first covered by a movable and normally colored integument; later this becomes dark-hued and livid. When spontaneously bursting, the rent of the gland capsule reveals a discolored grayish-yellow or darker admixture of thin pus and detritus of tissue, a healthy-looking wound being produced after scraping, which in well-managed cases proceeds without delay to repair. The scars left in either event strongly resemble those resulting from the similar process in tuberculous involvement of the lymphatic glands.

Actinomycosis should always be differentiated by the aid of the microscope; tuberculosis, if not by the same means, at least by the relative rapidity of evolution of the syphilitic process; for though at times but a few months are required for the entire career of the syphilitic lesion, the tuberculous are commonly far slower of career and soften centrally only after long delay. The lymphoma of syphilis rarely requires a twelvemonth for its completed curriculum. Carcinoma of the regions named is exceedingly rare; sarcoma is even more rare of occurrence.

The more lately devised methods of treatment in syphilis have not yet supplanted the older and approved devices, nor do they contain the promise of so doing. Tommasoli has employed intramuscular injections of a fluid obtained by keeping the blood of lambs for twenty-four hours on ice, separating thus the serum. From 2 to 8 c.c. of the latter are injected for a dozen or more times. The lesions of syphilis are reported to have rapidly and permanently disappeared under this treatment; and the reactive effects from these injections were in no case severe.

Wellander, of Stockholm, has employed for injections a mixture of the acetate of thymol mercury, gr. 1.5 in liquid paraffin, injected every fourth day till six or seven injections have been made. Indurations and abscesses at the site of the operation were minimized in number and severity; the reactionary effects were reported mild, and the symptoms of the disease yielded with varying but satisfactory promptness, some relapses occurring.

The other mercurial salts lately employed besides hydrargyrum thymolicum (thymolaceticum) are salicylicum, succinimidicum, alaninicum benzoatum, oxycyanatum, formamidatum. The basis employed by Schadek is an emulsion of gum arabic. The oxycyanide is used in injections of one-quarter of one per cent. The benzoate is employed in solution as follows:

Hydrarg. benzoat..................	0.30
Sod. chlorid........................	0.10
Aq. destillat........................	40.00

The succinimidicum is used also in one-per-cent. solutions.

Moncorvo and Ferreira report the treatment of a large number of young children affected with syphilis by hypodermatic injection, the corrosive sublimate being preferred by them for this purpose. The doses were exceedingly well tolerated by the children, who exhibited but little tendency to the after-occurrence of stomatitis, salivation, or intestinal colic.

Affections of the Eyes.—The *bones* composing the orbit may be involved in ostitis or periostitis, with degenerative results in the form of caries or necrosis. In this way may be lighted up an intra-orbital cellulitis resulting in abscess. Nodes also occur within the orbit, and may be followed by serious consequences when productive of pressure effects. The lachrymal passages also may be involved in obscure catarrhal changes, associated with pharyngeal lesions. Mucous and subcutaneous tissue, periosteum, and bone may be eventually implicated, with the result of producing lachrymation, epiphora, abscess, and eventually fistulæ. The treatment is by division of the canaliculi and dilatation of the canal by probes. The parts may then be treated with weak injections of the nitrate of silver, or, what is fully as valuable, two- to five per cent. solutions of resorcin. When the canal is pervious to the probe, the trouble is usually due to changes in the periosteum of the nasal process of the superior maxillary bone. The frequent application of water, as hot as can be borne, to the affected parts, if required in connection with the application of fomentations, will often give relief in these cases when energetic constitutional measures are adopted. Bumstead and Taylor report syphilitic changes in the lachrymal gland sufficient to produce a species of ptosis, and also gummata of the caruncles.

The *eyelids* may be severely and extensively involved in syphilis. They may be the seat of chancres, as also of papules, pustules, ulcers, and resulting cicatrices dragging the lids into ectropion. Syphilitic ulcerations attack the canthi and free edges of the lids, encroaching also upon the mucous surfaces. The author has seen both upper lids symmetrically involved in ragged ulcerations of the edge resembling the work of a punch. Degenerating gummata of these regions often leave disfiguring cicatrices. The palpebral conjunctiva is often the seat of mucous patches. Subcutaneous indolent nodules, the size of a hemp-seed to that of a pea, occasionally form in the lid, and they may obstinately persist when treated. The tarsus is reported also by several observers to have been involved in a tarsitis syphilitica, which is at first productive of tumefaction of the lids, and later of changes in the cartilage itself. The fasciæ and tendons of the ocular muscles are also liable to s philitic changes, which may result in thickening, in abscess, or in fistula. All syphilitic lesions of the eyelids are to be distinguished from chancres of the lid, accidents not of very rare occurrence in the large cities. In these cases there is great tumefaction, brawny, empurpled thickening (of the inner canthus usually, the part most apt to be rubbed by the finger that transports the infective secretion), and a specific induration of the preauricular or submaxillary gland—far more commonly the former.

The *conjunctiva* may be the seat of mucous patches, circumscribed macules, papules, tubercles, and gummata. These are, however, rare. The ocular conjunctiva is spared most of the lesions of syphilis, save when it becomes engorged with blood as a consequence of iritis.

The *cornea*, when participating in syphilitic changes, is usually recognized in the victim of inherited disease. There is found, first, slight pericorneal vascularization, in the diffuse form, with one or several centrally situated or marginal opalescent points showing in the cornea. These increase till the whole or a great part of the cornea is involved, producing thus a characteristic opacity limited to the field of the keratitis. With the keratitis of inherited syphilis are often seen the alterations in the color, size, and shape of the permanent incisor teeth, first described by Mr. Jonathan Hutchinson, who regards the permanent upper central incisors as the test-teeth. These are usually vertically and transversely shortened and thinned, with a crescentic notch at the free border, its convexity regarding the root of the tooth. This notching, most conspicuous in childhood, becomes partially obliterated by attrition in later life. The teeth are also often convergent, occasionally separated; in other cases "pegged," and again discolored in shades of a dull brown.

The punctate form of keratitis is seen both in acquired and in late inherited syphilis. Intracorneal puncta, the size of a pinhead, are then visible, careful observation of which reveals the lack of lustre or grayish shade of color of corneal opacities in general.

The *sclera* may be involved (1) in an episcleritis beginning with pericorneal hyperæmic macules of a dull-reddish hue, with few if any subjective sensations. A circumscribed portion of the sclera may then appear thickened, and in some cases radii of engorged conjunctival vessels indicate an extension of the hyperæmia to the overlying membrane. In extreme cases the cornea, sclera, iris, and lens are involved in a common inflammatory process; cases which the writer believes originate for the most part in an iritis. (2) An interstitial, or parenchymatous, scleritis may present the features of an inflammation of the organ, or of a gummatous deposit, or of infiltration within its substance, which, following the rule in similar involvement of other organs, may undergo resolution, or degenerate into an ulcer with irregular edges, and softish, grayish floor. When the cornea also is implicated, one sees a characteristic conical area of corneal opacity, its base resting upon the involved sclera, its apex projected forward to the centre of the cornea.

Iritis.—More than one-half of cases of iritis are of syphilitic origin, the proportion ranging between sixty and eighty per cent. of all cases. It is not only a common complication of the disease, but, as regards the loss of vision, one of the most disastrous. The symptoms of specific and non-specific inflammation of the iris are, taken *per se*, indistinguishable. Three forms are to be recognized: simple plastic, serous, and parenchymatous. The two first named belong to the earlier period of the disease; the last is due to a gummatous infiltration of the organ. The disease is commonly unilateral in situation at the outset, but in fifty per cent. of all cases ultimately attacks the other eye. It occurs most frequently at the average age of the syphilitic subject—that is, in early adult life; and is much more frequent in men, by reason of the greater exposure of the eyes of the male to the accidents incidental to the trades and occupations of life. Iritis is decidedly more frequent when special conditions in the environment of the patient favor the occurrence of the disease, as, for example, when the eye is exposed to the radiation of light from newly fallen snow in winter. Simple plastic iritis is the condition in which there is, first, hyperæmia and later a plastic exudate from some portion of the iris with proliferation of the connective-tissue elements. It may be so slight in its symptoms as to escape detection, and be then accompanied by mild photophobia and vascular injection. In other cases the symptoms are marked and distressing. There is distinctly pericorneal vascularization, sometimes subconjunctival œdema. The large, mobile, tortuous, brick-red conjunctival vessels contrast strongly with the straighter radii of delicate pinkish underlying vessels visible in the sclerotic zone and limited largely to it. Both planes of injection aid in giving a distinctly reddish color to the eye, which is evidently in a state of inflammation. The affected iris is peculiarly dull-hued, its color, as compared with its unaltered fellow, being changed in various shades according to the color natural to the organ in health. It is sluggish to the light, and often its structure is indistinguishable to the eye of the careful observer, because covered with a delicate stratum of the plastic exudate. The latter may extend also over the anterior capsule and give the pupil a cloudy appearance. The aqueous humor also may become turbid. In consequence of these changes the free border of the iris is often agglutinated, in various degrees, at one or several points, to the anterior face of the capsule of the lens, so that when its muscles contract the pupillary outline becomes irregular, being changed from the figure of a circle to that of an interrupted curve, or to semilunar, trefoil, figure-of-eight, or scallop shapes.

Serous iritis is characterized by the exudation of a serous fluid, with hypersecretion of a cloudy aqueous humor, which precipitates a deposit in the form of a delicate, opaque, punctate, or diffuse film on the posterior face of the cornea, the anterior face of the lens, and the membrane of Descemet. There is increased intra-ocular tension, the pupil is immobile and dilated, and the iris is changed in hue. There is less injection of the sclerotic zone than in the plastic form of iritis. Glaucoma may eventually result, from participation of the ciliary body and choroid in the process.

Parenchymatous, gummatous, or suppurative iritis affects the stroma of the organ, the cellular and vascular elements of which then proliferate, causing a regular or irregular increase in its dimensions. The attachments which form between the lens and iris are firm and unyielding. Tubercles, nodules, or "condylomata" (gummata), become visible as light- or dark-colored, circumscribed elevations on the surface of the iris, marginal or not in situation, sometimes vascularized as they persist, and attesting the unicity of the syphilitic process in all tissues of the body. Pus may form in the anterior chamber, especially in cachectic subjects.

The diagnosis of these disorders is not difficult, since their association with a syphiloderm, often papular, and the history of the case, usually corroborate the suspicion aroused by the lachrymation, pain, photophobia, and circumcorneal vascularization. The treatment is by the administration of mercury and the iodide of potassium internally, pushed until the system is controlled by these drugs; and by the instillation into the eye of the sulphate of atropine in solution (gr. ij. ad fl. ℥ i. [0.133–32]). In exceptional cases vesication over the temple may be employed with advantage, or a leech or two may be affixed near the ear. Opium hypodermatically, or cocaine locally, may be required to relieve pain. The oleate of mercury and morphine also may be applied by inunction over the brow, even where the mydriatic is employed. The eyes should be disused and protected against light (by a darkened chamber or shaded glasses). Paracentesis of the cornea and iridectomy may be required in severe cases at the hands of the ophthalmic surgeon.

A form of iritis has been observed in the first half-year of life of infants, mostly of the female sex, affected with inherited syphilis. It is both unilateral and bilateral, and accompanied by few of the marked subjective symptoms of the disease experienced by adults, but is far more liable to result in pupillary occlusion.

The *lens* is affected in syphilis chiefly by extension to it of inflammation of the delicate organs with which it sustains anatomical relations. Cyclitis, or inflammation of the ciliary body, is for the most part similarly excited by an iritis or choroiditis of the same eye. Very rarely, indeed, a gummatous exudation occurs primarily in its substance, and then commonly the iris is secondarily involved, with characteristic symptoms.

Choroiditis and Retinitis.—Plastic, serous, and parenchymatous inflammations of the retina and choroid are described by authors, the distinction between which forms, as also between inflammations of the two organs, is difficult to establish. The objective symptoms of these disorders, as recognized by the aid of the ophthalmoscope, may be described as increased vascularity, ecchymosis, opacity, œdema, and appearance in the fundus of the eye of whitish or yellowish spots. Often the pigment of the choroid atrophies, permitting in one or more places a view of the sclera through its tissue. Blackish areolæ may surround these irregularly bordered macules. In other cases the choroid presents the appearance of maceration; or again, circumscribed nodules (gummata) project above the general level. When there are distinct retinal changes, the point of entrance of the optic nerve is usually pinkish or reddish in shade, œdematous, and surrounded by distended and conspicuous vessels; or it is hidden from view by plastic deposits upon its surface, or by a fog in the vitreous humor.

The *optic nerve*, when affected with syphilis, is usually involved after extension to it of a retinitis or choroiditis. It is with great rarity primarily infiltrated with a gummatous product. The same is true of the vitreous, which is usually implicated only after syphilitic changes in its investing membranes.

Paralysis of the nerves of the eye is as nearly pathognomonic of syphilis as is iritis, from fifty to sixty per cent. of all cases occurring in syphilitic subjects. Many of these are early phenomena of cerebral syphilis, and hence amblyopia, failure of co-ordination of the ocular movements, and visual disturbances of every kind should be closely investigated at all times when occurring in the victim of syphilis. Paralysis of the third pair of cerebral nerves, the oculomotorius, is characterized by ptosis of the upper lid, external strabismus, and inability to move the globe upward, downward, or inward. Accommodation is wholly or partially lost, and the pupil is dilated. Paralysis of the sixth pair, the abducens, is, on the other hand, characterized by internal strabismus, amblyopia on the outer side of the vertical axis of the eye, and inability to move the globe outward. Paralysis of the fourth pair, the patheticus, is characterized by amblyopia for all objects lying below the equator of the globe of the eye, and by the fact that the patient is obliged to make an effort to correct the visual impressions of objects below that equator by the inclination of the head.

These paralyses may occur singly or in combination; and, with or without them, may be recognized monocular mydriasis, which, albeit occasionally associated with grave cerebral syphilis, the author has seen persist for years without impairment of co-ordination or other ocular symptom. Unquestionably these paralyses may be due at times to gummatous and other syphilitic changes in the membranes, periosteum, and bones within the cranial vault. Convergent strabismus is readily distinguished from paralysis of the sixth pair by the relief of the squint in the former case when the sound eye is covered. The treatment of these paralyses by the usual method of managing constitutional syphilis is, for the most part, encouraging. Tenotomy may be occasionally required.

The Eye in Inherited Syphilis.—In congenital diseases the lids, conjunctivæ, cornea, iris, choroid, retina, and optic nerve, may, one or all, be affected with specific inflammatory changes, or, more commonly, by gummatous deposits resulting in degeneration and ulceration. Grave ocular troubles in early life, especially if coexisting with persistent alterations of the subcutaneous structures, periosteum, or bone, should generally awaken the suspicion of syphilitic disease.

[For affections of the ear in syphilis consult the exhaustive article on this subject in Vol. III. (page 674)].

Affections of the Respiratory Tract.—*The Nose.*—The lining membrane of the nares may be the seat of macules, papules, erosions, mucous patches, and ulcerations, with catarrhal symptoms, the discharge from the nares becoming serous, purulent, or hemorrhagic. Inspissated masses of these secretions smeared with an offensive discharge are at times expelled. Gummata form in the same region, the degeneration of which leads to ulcerative changes in cartilage, periosteum, and bone. This order of sequence may be reversed, the gummatous infiltration first occurring in the osseous structure. The septum, floor, Eustachian tube, pharynx, roof of the mouth, antrum, and even the cerebral meninges, may be attacked by extension of the disease from one point to another. When the bridge of the nose is in this way undermined, a characteristic and highly disfiguring flattening occurs, which is rarely seen in any other disorder save syphilis, traumatism excepted. Cartilaginous destruction is productive of flattening of the tip of the nose. The practically remediless nature of these deformities renders the treatment of all nasal disorders in syphilis a matter of the highest consequence. When the antrum of Highmore is affected, there is a peculiar tumefaction, unaccompanied by coloration or change in the skin, of one side of the face, the treatment of which may require removal of a tooth, penetration of the floor of the antrum, and the wearing of an obturator for a time. When the Eustachian tube is involved, the drum membrane may be perforated and a purulent otitis media follow. Many of these changes, whether vegetative, erosive, or ulcerative in type, are accompanied by fetid ozæna, nasal phonation, and partial or total loss of the olfactory sense. Sometimes osseous fragments, varying in size from a hemp-seed to a finger nail, are discharged from the nares, the detritus of the carious process as it affects the nasal, turbinated, or other bones. Eburnation and thickening of the bones *in situ* may also result. The internal treatment of these cases is by mercury, iodide of potassium, the mineral acids, and ferruginous tonics. Locally, the treatment may be successfully conducted by the aid of mercurial fumigation, but the use of a cleansing douche, followed by lotions containing the bichloride of mercury, resorcin, iodized phenol, potassium chlorate, or boric acid, may be preferable.

The Larynx.—The vocal cords, arytenoid and glosso-epiglottic folds, and all parts of the mucous, submucous, cartilaginous, and osseous tissues of the larynx, may become the seat of syphilitic changes. Diffuse circumscribed erythema, mucous patches, papules, "condylomata," vegetations, erosions, and gummata may be followed by superficial or deep ulcerations, circumscribed or extensive infiltrations, and cicatrices, the contracture of which may induce grave and dangerous laryngeal stenosis. Pain, cough, changes in the volume or pitch of the voice, dyspnœa and dysphagia, are not at first noticeable. The supervention of œdema may gradually or rapidly usher in a serious condition. Later, when stenosis of the larynx (the more frequent of the ultimate results) is induced by cicatricial contraction, or (more rarely) by vegetations, false membranes, gummata, or nodes, the voice may be reduced to a whisper, or there may be complete aphonia, dysphagia to a slight extent, or dyspnœa even to a grade demanding tracheotomy for the preservation of life. The mucous membrane of the larynx is affected also with a chronic form of infiltration, which results in a characteristic induration of the important submucous tissues of the larynx, distinguishable from œdema by its firmness and density. The deeper ulcerations of this organ resulting from degenerating gummata, circumscribed or diffuse in extent, commonly spread from similar lesions in the pharynx, resulting ultimately in destruction of the epiglottis, leaving often in such cases a single wide and ragged laryngo-pharyngeal chasm; or involving the cords, aryteno-epiglottic ligaments, and deeper structures. When the cartilage is involved, crepitation is said to be perceptible after the occurrence of perichondritis; and sequestra have been removed when caries or necrosis has attacked the ossified cartilage. Syphilitic aphonia, obscure as to its immediate cause, as well as paralyses whether of one or both sides, is not to be confounded with syphilitic aphasia. Tuberculosis can now be satisfactorily differentiated from these affections by the modern methods of recognizing the bacillus of that disorder, as well as by the other signs of phthisis and the absence of a history of syphilis and its concomitant symptoms.

The trachea may become the seat of lesions similar to those recognized in the larynx; but the absence here of the delicate mechanism required for phonation explains why they are rarer, less conspicuous, and less complicated. The larynx, trachea, and bronchi are usually simultaneously or successively involved, the trachea alone very rarely. All the lesions of mucous surfaces in syphilis, all the vegetations, infiltrations, and degenerations, may here be noted, including extratracheal abscesses from perforation. Stenosis from cicatricial contraction may here also induce fatal results. The internal treatment of laryngeal and tracheal syphilis is that of the disease in general. Locally, the parts may be wiped with solutions of boric acid, benzoin tincture, eucalyptol, or dusted with iodoform, or tannin in fine powder, reduced if desired. The galvano-cautery is best employed in the surgical management of membranoid occlusions, which are, it should be remembered, quite uninfluenced by large doses of the potassic iodide. The last named drug is indeed, in some cases, credited with producing a form of laryngeal œdema. Dilatation with bougies has not won for itself much favor in the management of these cases. The use of tobacco, both by smoking and by chewing, is to be interdicted in all cases.

The bronchi may become the seat of the syphilitic changes described in connection with the larynx and trachea. Few cases, however, have been carefully studied, though stenosis following ulceration has been recognized post mortem.

The lungs may be the seat of a syphilitic infiltration affecting usually one side of the chest only, and then the upper, middle, or lower lobe. The pulmonary tissue becomes so dense in these cases as to be impermeable to the air; and yellowish points are visible here and there in the relatively small patch of consolidation, due to the irritation of the parenchyma by the sclerotic nodule.

These sclerosed portions of the lung by their contraction induce either stenosis or ectasia of the normal canals and chambers in the vicinage. Under the microscope the sclerosis is seen to be made up of bundles of firm connective tissue, between which appear stellate, fusiform, and roundish cells, with a granular detritus. The vessels of the part are first engorged with blood, and later choked with the stasis of their contents.

Pulmonary gummata, or circumscribed syphilomata, of the lung rarely form at the apices of these organs, but are found in all other parts. They are grayish, semi-solid masses, varying from the size of a pea to that of an egg, set in the pulmonary parenchyma, surrounded always by an opalescent, fibrous, basket like capsule, and as they grow older they often exhibit one or more yellowish points in their mass where caseation has begun. Softening progresses from centre to periphery, and the contents may find exit by the portal of a neighboring bronchus with a secreting cavity left behind; or resorption may occur with the result of leaving in the lung tissue a fibrous mass, having a cheesy centre. These conditions may be found in one lung: gummata forming in cavities originally resulting from lesions that have degenerated, mingled with fibrous sequelæ of resorption, and contracting cicatrices. Often the pleura and bronchi are either involved in the same process or exhibit the irritating effects of the pulmonary neoplasms. Microscopically, the centre of these gummata is found to be made up of granular connective tissue, in process of degeneration, and highly refractive granules. The fibrous tissue is concentrically wrapped about them, the cellular elements nearest the core having undergone in part fatty metamorphosis. Still more externally lie irregular masses representing a small-celled infiltration, which in places blocks up the alveoli. The lesions are encircled by peripherally distributed connective tissue with clearly defined limits. The result, as regards the lung tissue, is, according to Councilman, a pneumonia with fibrinous exudation, accompanied by fibrous thickening of the alveolar walls, the whole undergoing caseation. When the action of the virus is intense, necrosis of tissue occurs before there is time for the development of the protecting connective tissue.

The analogy between tuberculosis and syphilis of the lung is shown by the fact that in both processes a caseous pneumonia results; but in the former instance the inflammatory process is the direct result of the presence and irritative effects of tubercle bacilli; in the latter, the primary process is an atrophy of the alveolar walls, most probably due to a hyaline degeneration of the capillaries.

The diagnostic differences, as given by Delafield, are, in syphilitic disease of the lung, dyspnœa on inspiration; a varying degree of supra- and infraclavicular retraction; on percussion, marked dulness over the affected parts; on auscultation, prolonged and high-pitched respiratory murmur, with a pause between it and a prolonged and almost equally high-pitched expiratory murmur. Sibilant, sonorous, crepitant, and subcrepitant râles are often wanting; vocal fremitus on coughing is increased. The symptoms of these lung changes of syphilis are largely those of non-specific inflammatory disorders, viz., bronchial catarrh with expectoration of muco pus; diminution of sonority in percussion; limitation of the respiratory area in affected parts of the lung; dry and moist râles; prolonged expiration, and dyspnœa. Cases of severe hemorrhage in patients affected with syphilitic pulmonary sclerosis may go on to complete recovery after appropriate therapy. In the event of degenerating gummata of the lung, the symptoms are those of pulmonary caverns, whatever be the cause, hollow gurgling râles, pectoriloquy, raucous voice, etc. The diagnosis is established by the history of syphilis and by any concomitant symptoms present; by the relative immunity of the pulmonary apex; by the smaller number and larger size of gummata, as contrasted with miliary tubercles; and by the absence of the bacilli of tuberculosis, of the signs of hydatid cysts, and of neoplasms of other diseases. The treatment is that of syphilis in general, with such remedies as are specially indicated by the pulmonary symptoms present.

Affections of the Digestive Tract.—*The Mouth.*—As the lining membrane of the mouth is more often exposed to the eye of the practitioner than any other mucous surface in the body, the symptoms which it exhibits in the victim of syphilis may be regarded as representative of mucous lesions in general. They are all properly in alignment with the cutaneous lesions, the modifying influences being chiefly heat, moisture, and motion; the latter incidental to the performance of the important functions of the mucous cavities. Thus the buccal cavity is often the seat of diffuse or circumscribed erythema, in dull red shades, faucial or palatal in situation, with defined or irregular outlines, accompanied by infiltration, œdema, and often by erosions. These may be multiple, pea-sized patches, or a single sheet of diffuse blush. The former, after maceration, may, by either a vegetative or a degenerative process, form papules, mucous patches, or ulcers. In malignant cases a dull-red erythema often precedes the gangrenous crateriform ulcer which opens, almost as at a stroke, the oral and nasal cavities by a communicating chasm.

Mucous Patches (Mucous tubercles, Plaques muqueuses, Moist papules, etc.).—The larger number of these lesions appear in the mouth and about the anus, though they are to be seen near all the mucous outlets of the body. They are far more common and more severe in the mouths of men than in those of women, on account of the tobacco habits of the former. They are early and late lesions of syphilis, and are represented in the symptoms of relatively few diseases not syphilitic. They consist of roundish, oval, or irregularly shaped discs, or longer, narrow, indefinitely outlined bands of a delicate rosy hue; grayish or opalescent in color; often granular and elevated about a millimetre above the general level of the surface where they appear. Many of them seem to be covered with a delicate pellicle. When of a pinkish or reddish shade, they represent merely a stage of hyperæmia of the membrane; when opalescent, as if pencilled by the silver crayon, a stage of maceration of the previously infiltrated epidermis; when granular, a stage of attempted repair, the loosened pellicle having been removed by friction or otherwise, and the surface beneath forming a new epithelial envelope. They may form upon a chancre when undergoing its so-called "transformation *in situ*," already described. When located in quasi-mucous situations, viz., those portions of the skin in the vicinity of the mucous outlets subjected to friction and kept moist and warm (inner faces of the thighs, inside of the toes, etc.), they may vegetate and produce the condyloma, a lesion frequently seen about the anus and genital region, more particularly in syphilitic women of filthy habits. These are usually circumscribed, multiple, roundish, or irregularly shaped, wart-like elevations, smeared with a whitish mucus, highly contagious, and of especially disgusting odor when seated about the ano-genital orifices. In the same situation they are remarkable for the production of a sensation of itching, rarely awakened by other syphilitic lesions. Occasionally they are dry. They are, as a matter of fact, merely papular lesions, flattened by apposition of the surfaces between which they are developed, or vegetating, as the clefts in these same surfaces permit of such a growth, secreting because moist and macerated, and itching because irritated by the same agencies. When exposed, as about the bearded lips and nares, they are dryer, and browner, or duller red in hue. They occur in and about all the mucous outlets, and affect all mucous surfaces, with a marked predilection for the neighborhood of the muco-cutaneous borders. They are common in both infantile and inherited syphilis. They may become cracked, eroded, and superficially or very deeply ulcerated. Their excessive proliferation may produce enormous masses of secreting, wart-like, softish growths, described by authors as frambœsioid condylomatous syphilodermata.

The mucous patches of the mouth are less elevated and more opalescent than others, and appear upon the inside of the lips and cheeks, gums, uvula, palate, tonsils, and pharynx. They should never be confounded with the transitory, minute, usually distinctly circular, aphthous ulcerations to be seen in healthy adults after a fit of indigestion; nor with the persistent, much firmer, leathery discs, or striated or ribbon-like streaks, described as psoriasis linguæ, leukoplakia buccalis, etc., which, as is now well known, may be the earliest epitheliomatous transformation of a mucous membrane; nor with lichen planus of the mouth; nor, lastly, with the so-called "smokers' patches" (plaques des fumeurs, etc.), which many cases, it can scarcely be questioned, represent buccal lesions in a veteran of syphilis.

The tongue may display a wide variety in the lesions of syphilis. In the order of gravity may be named: Multiple, macular lesions, the size of a pinhead, abundantly spread over its upper surface; mucous patches in all forms, particularly over the edges and tip, often forming where the organ is rasped by the rough edge of a carious molar tooth; flat, circular papules, the size of a bean and larger, elevated a millimetre or two above the general level; circumscribed and diffuse, superficial or deep (parenchymatous) scleroses, usually developed upon the upper surface of the organ and near its mesian line, characterized by irregular increase of bulk and almost cartilaginous density, which may result in resorption and atrophy or ulceration; and, lastly, superficial or parenchymatous gummata, submucous or muscular in site, occasionally single, often multiple, which also may disappear by resorption or degenerate by ulceration. One of the remarkable features of disintegrating syphilitic, as distinguished from other neoplasms, of the tongue is the relatively slight damage apparent after completion of repair. These all are to be distinguished from epitheliomata, which are more voluminous, more hemorrhagic, less deeply excavated, more irregular in mass, and more painful; as also from colloid lingual tumors (so-called "hygroma" of English authors), with the appearance of vesicles on the upper surface and enormous asymmetrical increase in the bulk of the organ in childhood; and, lastly, from tuberculosis of the organ, rare of occurrence, to be recognized only by its histological characters.

The *maxillary bones* may undergo necrosis as a result of syphilis. The most common site of the accident is the central part of the dome of the hard palate. There is first a dull-red erythematous swelling of the membrane and submucous tissue, which in severe cases may seem to give way like wet paper, leaving a conical perforation through which communication is opened between the oral and nasal cavities; in other cases an abscess forms and bursts, after which the bone is laid bare and exfoliates in larger or smaller masses from time to time. Necrosis of the alveolar processes usually occurs in the upper law. Gummata of the soft palate often form insidiously, are circumscribed or diffuse; at first firm, later softish, tumors, varying from the size of a pea to that of a small nut, or in patches of thickening. Absorption or ulceration may result, and the latter often rapidly, in consequence of the lax and unsupported tissues involved; the process in grave cases opens (by destruction in whole or in part of the uvula, pillars of the fauces, and velum) a wide chasm between the fauces and the posterior nares. Interference with the Eustachian tube often produces temporary deafness. The voice is disagreeably nasal, deglutition is often difficult in the erect posture (patients with extensive tissue-loss will often assume unusual postures, by which they can even succeed in swallowing liquids without the passage of the latter into the nose), and the pain in general is quite disproportionate to the severity of the damage. Marvellous are the reparative results when, as is usually the case under sound management, repair ensues. The remaining fragments of the velum palati contract adhesions to the posterior pharyngeal wall, the chasm contracts, and the expert can trace the picture of the mischief that has occurred when inspecting only the narrow and distorted chink left after contracture is complete.

Fournier only has reported a case of syphilitic involvement of the sublingual gland.

The *pharynx* may become the seat of macules, papules, mucous patches, gummata, and ulcers, which in many cases are formidable. The latter may spread from the posterior nares and extend downward into the œsophagus, or backward, so as to produce destructive effects upon the periosteum of the vertebræ and the structures they protect. Occasionally, patients long neglected or badly treated, exhibit gigantic caverns, including what were once the nasal, buccal, and pharyngeal cavities, the whole lined with a granulating or secreting and ulcerated membrane. Even in those extreme cases in which one is disposed to wonder even at the prolongation of life, repair ensues and emphasizes the striking, almost pathognomonic, distinction between the damages inflicted by syphilis and many other destructive diseases.

The *œsophagus* is said to be very rarely the seat of syphilitic lesions which, after ulceration, may produce stricture, either spasmodic or organic, resulting in serious danger to life.

The *treatment* of all these lesions is practically the same. Internally, mercury and the iodide of potassium are essential, the latter often in the largest permissible doses, to save important organs. Care of the patient's nutrition is in most cases imperative. Locally, the nitrate of silver, sulphate of copper, chlorate of potash, tannin, resorcin, acid nitrate of mercury, nitric acid, and tincture of iodine may be employed in strength varying according to the requirements of each case—the first named in solid stick or solution of a strength of from five to sixty grains to the ounce (0.33–4.0 to 32.0). By spraying, pencilliog, dusting, washing, and gargling, these preparations may be used, with the greatest advantage, a number of times throughout the course of the day. The following are excellent formulæ for gargles:

℞ Potass. chlorat............... ʒ i. (4.0)
Mel. despum.,
Myrrh. tinct...............āā fl ℥ ss. (16.0)
Aq. des.................ad fl ℥ iv. (128.0)
M. S. Gargle. Use diluted as required.

℞ Potass. chlorat.................. ʒ i. (4.0)
Infus. lini...................... O i. (500.0)
[Bumstead and Taylor.]

℞ Acid. carbolici................ ʒ i. (4.0)
Glycerin,
Spts. vin. rectif............āā fl ʒ ij. (8.0)
Iodin. tinct.................. fl ʒ ss. (2.0)
Aq. dest..................ad fl ℥ i. (32.0)
M. Five to fifteen drops in a third of a tumbler of water for gargle or lotion.

The toothbrush, in all cases, is to be regularly employed twice daily; if the patient is unaccustomed to its use the mouth should be well cleansed and the gums rubbed with a bit of soft muslin on the finger, dipped in water to which a few drops of the tincture of myrrh and cinchona have been added. Tobacco is to be, in every form, absolutely interdicted; and all very hot and very cold, and irritating articles of diet are to be excluded (*e.g.*, hot coffee, ice cream, vinegar, spirits, spices, etc.).

The stomach and intestinal canal may become the seat of syphilitic lesions of the type seen upon the other mucous surfaces. Huet, Cornil, Klebs, and others report gummata of this part of the digestive tract; Leudet, Virchow, and Fauvel describe diffuse infiltrations of portions of the tube; Engel, Fioupe, Cullerier, and others, perforating ulcers (probably due to gummata) as also scleroses resulting in contracture, even productive of irritation sufficient to light up a peritonitis near a stricture of the colon. It should not be forgotten that a long list of functional disorders of the alimentary canal might be enumerated as of occurrence in the syphilitic subject, which are often due to the toxic influence of the disease (cachexia, etc.); to the effect of certain of the medicaments ingested or externally applied for its relief; and to improper alimentation or hygiene.

The rectum may become the seat of a series of important changes due to syphilis. Women are more liable to be thus affected than men in the proportion of eight to one, a preponderance which has been referred to the anatomical differences between the sexes, to the physiological fluxes of women, previous pregnancies, and to unnatural or excessive coitus. Chancroids, occurring as they do frequently about the anus of women, may result in induration of the submucous tissues, accompanied by purulent and sanguinolent discharges, constipation, or looseness of the bowels, and painful defecation. This condition is to be carefully distinguished from syphilitic stricture of the rectum.

The syphilitic affections of the rectum may, perhaps, include the category of syphilitic lesions of mucous surfaces in general. The most important, however, are those characterized by ulceration or gummatous changes. The former may extend from without inward, from the perianal region to an inch or more within the sphincter; or may begin by one or several points of ulceration in the latter situation. The so-called "ano-rectal syphiloma" is a cylindriform, gummatous, non-ulcerated infiltration of the entire circumference of the ano-rectal walls, capable of producing stricture by transformation into fibrous tissue. It is, however, an error to suppose that stricture of the rectum not due to chancroids, but syphilitic in character, always conforms in type to the syphiloma. The author has treated a middle-aged woman, whose husband and two children are victims of severe syphilis, and whose left lower extremity is extensively seamed with perfectly typical syphilitic cicatrices. There are in this case four abscesses in the nates, communicating by fistulous sinuses with the bowel and vagina, the syphilitic stricture of the rectum being represented by a sharply defined, thin, annular coarctation of the rectal wall, with a submucous gummatous infiltration strictly limited to the ring of the coarctation. It is evident that only in exceptional cases, probably during the period before contracture has set in, can internal medication accomplish practical results in these cases. Dilatation or division of the stricture by the knife or galvano-cautery is usually required, with free opening of all abscesses and sinuses, and observance of strictest antiseptic precautions with bichloride dressing. Often the production of an artificial anus in the abdominal wall is imperative. The future is, however, often unpromising for these cases, many women who are the victims of the disorder having their health profoundly impaired by previous suffering and disease.

The liver, like the intestinal canal, may suffer, when invaded, from functional disorders, which may depend upon slight structural changes participating in the process which results in the cutaneous exanthem. The icterus probably originating in this way, which may somewhat precede or accompany the first syphiloderm, has already been described. It may be accompanied by hepatic congestion and by symptoms of malaise, hebetude, cephalalgia, and even slight pyrexia. The late forms of syphilitic involvement of the liver are well marked. General, more commonly partial, interstitial hepatitis, affecting chiefly the capsular and ligamentous attachments of the organ, produces a distortion of the gland by contracture of fibrous bundles which, springing from these attachments, penetrate the hepatic parenchyma and divide it into uneven lobulations and irregular masses separated by furrows. There is at first increase, and later diminution, in the bulk of the organ, with the usual symptoms of cirrhosis. Hepatic gummata are of more frequent occurrence, and in "galloping" cases may be seen within six months after infection. They are usually grouped in clusters of from six to a dozen lesions, varying in size from a large pinhead to a small nut. Centrally they contain roundish cells and granules in a delicate connective-tissue reticulum, surrounded by a fibrous envelope, and embedded in dense hepatic tissue. The symptoms in mild cases are probably scarcely sufficient to indicate the nature of the affection. In others, disturbance of the alimentary canal (icterus, constipation, dysentery); pain in various degrees, limited to the hepatic region or radiating from it; and, very rarely, morbid changes perceptible on palpation of the enlarged, or previously enlarged and subsequently shrunken, organ, may first point to the precise nature of the trouble.

Gummata of the liver are to be distinguished from hydatid cysts; carcinoma (of advanced years); hepatic abscess (in persons who have been long resident in tropical countries); tubercles (usually softer, more cheesy, more purulent in the centre); and the rare forms of sarcoma of the liver. The prognosis of hepatic syphilis is usually not grave.

Amyloid degeneration of the liver may be the result of syphilis as of other diseases. There is increase in the bulk of the waxy-looking organ, the hepatic cells becoming enlarged after involvement of the swollen hepatic capillaries. Often there are coincident amyloid changes in the heart and spleen. The symptoms of hepatic gummata are as obscure in many cases as in syphilitic cirrhosis. There may be ascites, hemorrhage from the portal vein, and dyspnœa. The treatment is largely that of syphilis in general.

The spleen often enlarges in those early periods of syphilis when the lymphatic glands tumefy. Commonly the enlargement subsides as the disease progresses or is modified by treatment. Syphilomata of the spleen (gummata) are rarely observed, but have been recognized in both circumscribed and diffuse forms. Splenic gummata are yellowish, softish nodules, from the size of a pinhead to that of a small nut, set in a dense splenic tissue of unusual dryness. In diffuse forms, the organ appears to be in part hypertrophied and dark brown in color. Later, islets of grayish sclerosed tissue become apparent in this mass, the involution of which leaves cicatriform depressions. Rarely a perisplenitis may be lighted up by these changes, leading to the formation of whitish patches of almost cartilaginous density. The clinical symptoms of syphilis of the spleen are obscure.

The pancreas is said to be occasionally the seat of changes supposed to represent the circumscribed and diffuse syphilomata recognized in the liver and spleen.

Affections of the Circulatory Organs.—*Myocarditis*, recognized chiefly in post-mortem examinations, may be a late complication of syphilis, which affects men more often than women in the proportion of six to one. Softish, yellowish gummata, from the size of a nut to that of an egg, as well as circumscribed and diffuse sclerosis, have been recognized in the ventricular walls and auricles of both sides. Plastic or fibrous metamorphosis of the muscular tissue about any of these lesions may occur. Whitish diffuse infiltrations, firm, or of the consistence of a sarcoma, with round-celled infiltrations and vegetations, may affect the endocardium or muscular tissue; and the same changes in the pericardium may result in partial or total obliteration of its sac. These commonly originate in subendocardial or subpericardial gummata. Wagner, Lancereaux, and a few others have reported gummata limited to these serous membranes. The symptoms excited by these changes are dyspnœa, palpitation, cyanosis, præcordial distress, and angina pectoris. The prognosis is naturally grave, since all the identified instances of this affection were recognized in the bodies of the dead. It is reasonable, however, to suppose that syphilis here, as elsewhere, exhibits its usual amenability to treatment in the case of patients with symptoms not diagnosticated in life.

Arteries and Veins.—The femoral, jugular, saphena, and other veins may be affected with a phlebitis due usually to the pressure exercised by a gummatous tumor in the vicinity. A sclerous phlebitis, in which the intima was first attacked, has also been recognized post mortem.

The capillaries and arteries also may be primarily or secondarily involved. In the latter case the result is commonly due to compressive or destructive effects exerted by syphilitic processes upon adjacent organs. Syphilitic endarteritis, however, is much more common; and investigation by Virchow, Heubner, and others has revealed its pathology with sufficient clearness. The lesions are more commonly observed in the smaller cerebral arteries, but the carotids and other vessels are occasionally involved. The definite limitation of the disease to a single patch is declared by the rapid appearance of whitish, opaque nodules, the size of a millet-seed, composed of small, roundish, or spindle-shaped cells, which may be agglomerated into a firm, fibrous mass, from the size of a pea to that of a nut, obliterating the lumen of the invaded artery by thickening of all its investing coats, and producing eventually either rupture or an atrophic or cicatriform relic of its existence. This infarction is remarkable for the indirect results which it produces, including cephalalgic, aphasic, paretic, paraplegic, and even comatose symptoms.

The Genito-urinary Organs.—Symptoms of syphilis are disclosed in the genito-urinary tract of patients of both sexes, early and late in the course of the disease.

The penis may become, in one part or another, the seat of circumscribed syphilitic infiltrations and gummata.

Lesions of this nature may be subcutaneous, or there may be nut-sized masses deeply lodged in the substance of the corpora cavernosa, or in the submucous tissue of the urethra. Some of the lesions discovered post mortem, and described as "chancres of the deep urethra," are really tertiary ulcers resulting from broken-down gummata of the prostatic or membranous urethra. Jullien figures a cavern of the cutaneous surface of the penis originating in this way in one of Langlebert's patients. Tubercles of syphilitic origin may be developed near the furrow at the base of the glans.

Each part of the *testicles* may be affected with syphilis.

The epididymis, when involved, may display either an early or a late form of syphilitic epididymitis.

The early form, first described by Dron, in 1863, may be observed at any time between the third and thirtieth months after infection. The disorder bears no relation to gonorrhœal epididymitis. The globus major, or head, of the organ, much more rarely the globus minor, is attacked and either insidiously or acutely affected, producing a roundish or squarish, circumscribed tumor, from the size of a bean to that of a small nut, which has been compared to a "monkey-nut screwed to the testicle." One or both organs may be involved, successively or simultaneously, and the globus minor may be attacked later. The affection is amenable to treatment, and commonly disappears without unfortunate sequelæ.

The late form is often connected with gummatous changes in the testis proper, but very rarely arises independently of the latter. Here also the globus major is more often attacked; and resolution, as is the case with deposits in the testis proper, may be followed by atrophic changes.

Syphilitic *orchitis*, sarcocele, or albuginitis, may be a relatively early or late symptom of syphilis, involving one or both organs simultaneously or in succession. In these cases, the body of the testicle is involved, often without the production of pain, in a smooth, uniform, and firm swelling, which may be due in part to enlargement of the testicle, and in part to a moderate grade of hydrocele concealing the irregularities perceptible later in the body of the organ. In other cases, this body can be recognized by palpation as the seat of one or several masses, from the size of a pea to that of a small nut, which may be at first isolated and circumscribed, but later become fused into a solid, resisting mass having the general shape of the testicle, but often three or four times larger. Under energetic treatment, resolution of these masses is accomplished; but obliteration of the vasa deferentia and atrophy, or fatty, fibrous, cartilaginous, amylaceous, even osseous metamorphosis of the parenchymatous tissue of the gland may follow the absorption of the neoplasm. In this way the testicle may be, after completion of this cycle of changes, represented by merely a bean-sized mass of fibrous tissue. Suppuration and ulceration of the tunics almost never result, though a few authors have reported a resulting "fungus of the testicle."

Pathologically studied, the glands are found to be the seat of vascularization and proliferation of connective tissue, resulting in the production of fibrous trabeculæ traversing the organ in various directions, but always attached to its thickened investments, resulting by contracture in compression and atrophy of the secreting cells of the tubules. In other cases, true, grayish or yellowish gummata are found in the testis, single or multiple, diffuse or circumscribed, from the size of a pinhead to that of a pigeon's egg, environed by fibrous capsular coats. These commonly disappear by absorption; even in the rare cases of disintegration and the formation of "fungus of the testis," recovery ensues under proper treatment.

All syphilitic lesions of the epididymis and testis are to be distinguished from the gonorrhœal, the cancerous, the sarcomatous, and the tuberculous. The blennorrhagic affections of the epididymis are acute in type, painful, attack the tail of the organ by preference, and are usually preceded by an unequivocal history of urethritis and discharge. The neoplasms of cancer and sarcoma in the testicle, more often occurring in subjects of advanced age as contrasted with the younger victims of syphilis, are usually accompanied by inguinal adenopathy, severe pain, systemic cachexia, extensive damage to the parts affected, and proneness to disintegration. Tuberculosis is more common in young men virgin of all venereal antecedents, usually with tuberculosis of the prostate gland and marked dysuria. The bacillus tuberculosis may be recognized in the secretion obtained by "milking" the prostate. The treatment internally is by the potassium iodide and mercury. Locally, suspension of the organ is to be recommended; hot fomentations for relief of pain when such exists; and applications of salves containing lead, mercury, belladonna, or opium. The oleate of mercury and morphine, mercurial plaster, white precipitate salve, or the compound iodine ointment may be applied. Strapping, as employed for relief of gonorrhœal epididymitis, may be practised with advantage in some cases. The prognosis is not unfavorable as regards the health of the patient; but, after double syphilitic orchitis, the patient may have complete aspermatism. The *prostate gland, vasa deferentia, common ejaculatory ducts*, and *vesiculæ seminales* are all the seat at times of syphilitic changes, the characters of which are not known.

In women the *labium majus*, usually one, occasionally both, may be the seat of gummatous changes due to syphilis. These may be late and unique manifestations of the disease. Often nothing can be gathered in cases of this sort as to the history of syphilis, a not uncommon experience in the infected of that sex. The organ is found, when examined, to be wholly or in part the seat of a dense, smooth or irregularly lobulated, vertically disposed tumor, very closely resembling in size and external appearance a scrotum containing a testicle affected with syphilitic orchitis. Syphilitic gumma of the vulva is usually an exceedingly indolent affection, lasting for long periods of time, rarely occurring at the outset till three or four years have elapsed since infection. It is often diagnosticated as "elephantiasis" of the labium. Disintegration of the mass by ulceration is rare.

The syphiloma of the vagina is similar to the lesion described above in the date of its occurrence, its exceedingly indolent career, and its existence for months without a single coincident symptom of syphilis to substantiate the diagnosis. Many of these cases have been recorded, treated, described, and even illustrated as "lupus of the vulva," or "of the vagina," which disorder is even rarer than this exceedingly rare manifestation of syphilis. When recognized, the vagina is converted into a thickened cylinder of tissue infiltrated with gummatous material, which greatly restricts the distensibility of the vaginal walls. In some of these cases the finger can with great difficulty be introduced into a channel through which viable infants have been ushered into the world. Irregular projections of the inextensible vaginal membrane, club-shaped, knobbed, granular, eroded, or ulcerated, represent points where the larger submucous gummata are undergoing extreme development or ulcerating. These lesions break down more frequently and more disastrously than do the gummatous metamorphoses of the labia. Occasionally the ostium vaginæ is converted into a vast gummatous ulcer, invading the vestibulum and even the urethra. In severe cases the rectum participates in the change.

The neck and body of the *uterus* exhibit more rarely and to a much less marked degree similar changes; induration, tumefaction, erosion, and ulceration of the mucous lining are reported by authors.

The Fallopian Tubes and Ovaries.—Lancereaux and Lecorché, respectively, have reported instances of diffuse and gummatous changes in the ovaries. In the case reported by the first-named author, there were two egg-sized tumors with long diameters parallel with the broad ligament. Bouchard and Lepine, quoted by Jullien, describe a single case of syphilitic salpingitis.

The kidneys undergo changes both in early and in late syphilis. The phosphates and chlorides may be unchanged in the urine; urea may be quantitatively in excess, and albumin occur in quantities as great as in Bright's disease. Severe albuminuria following syphilitic changes in the kidney and even extensive anasarca following may be satisfactorily relieved by treatment. Glycosuria has appeared and disappeared under precisely similar circumstances in syphilitic subjects. By some authors, these several conditions are claimed to be the results simply of the cachexia which may affect syphilitic as well as non-syphilitic patients, producing thus the amyloid, waxy, and other metamorphoses recognized in other cases. Without denying the possibility of such accidents, the striking fact remains that some of these cases bear the special imprint of syphilis in that, after the exhibition of alarming symptoms, a complete, rapid, and permanent recovery may ensue after energetic treatment by mercury and, more often, by the iodide of potassium.

Syphilitic sclerosis and gummata of the kidney are late lesions of syphilis, and of rare occurrence, the last named being decidedly the rarer of the two accidents. In the diffuse form of syphilitic nephritis there is usually a cycle of vascularization and tumefaction of the cortical portion, followed by interstitial proliferation, attachment of capsule to cortex, and formation of irregular, small, or large nodules and projections from the surface, the exterior gross appearances of which suggest the similar lobulations of the syphilitic testicle. In some places these undergo lardaceous, amyloid, and other degenerative changes resulting in cicatrices. Precisely as the seminiferous tubules of the testicle are choked and eventually reduced to atrophy, the glomeruli and uriniferous tubules of the kidney may be compressed, their channels obliterated, and their functions arrested. Here and there, on section, yellowish points or streaks of fatty metamorphosis are visible upon a granular surface; or the totality of the organ may be changed to a dead-whitish color.

Gummata of the kidney are developed in both the cortical and the pyramidal portions. They are single or multiple, grayish or whitish, definitely circumscribed masses, from the size of a pinhead to that of a pigeon's egg, with a whitish or reddened and vascular, fibrous envelope like a capsule. The centre is firm or cheesy, according to the age of the gumma; and the body of the lesion is made up of elements derived by proliferation from the connective tissue of the renal stroma. The subjects of these several complications of syphilis may suffer from vague pains, changes in the eye, peritoneum, pleura, and nervous centres, as well as ascites, anasarca, lumbar pain, hæmaturia, and albuminuria. The prognosis is decidedly less grave than in non-specific renal affections of similar type.

The Nervous System.—Affections of the nervous system may be early or late symptoms of syphilis, and are commonly the results of morbid changes in contiguous structures, such as bone, vessel, or investing membrane. They are much more common in men, chiefly because of the greater tax levied upon that sex in the demand for physical and mental strain.

The literature of nervous syphilis, most of which has been contributed during the last twenty years, has been both voluminous and valuable. In the following paragraphs it will be possible merely to trace the outlines of the important advances which have been made in this special field. The clinical pictures presented may be briefly named as follows:

Headache, insomnia, and irregular performance of functions of many of the organs of the body (eye, ear, heart, muscle, liver), dependent upon nervous disturbance, are not infrequent in the early periods of syphilis. The headache of this stage of the disease is often persistent and obstinate. It may be frontal, temporal, or occipital in situation, and of the moderate grade from which few infected subjects are wholly exempt, or severe, with intense nocturnal exacerbation, eliciting groans from the sufferer. This distressing complication of the disease may endure for only a few days, or last for weeks or months, proving eventually a mere precursory symptom of cerebral syphilis. Without question these symptoms are often recurrences or exaggerations of morbid states existing previous to infection by the subjects of hysteria, alcoholism, other cerebral affections, and epilepsy. Mild nervous manifestations may be recognized, including anæsthesia, analgesia, circumscribed hyperidrosis, and hypertrichosis, and cutaneous sensations of coolness, heat, formication, and tingling. Many of these features are such that the pathological changes on which they depend are necessarily unknown, or can be estimated only by reasoning from analogy. The supposed cerebral syphilis *sine materia* has for its basis only the non-recognition of structural changes where autopsies were made after the exhibition of well-marked nervous symptoms. In such cases, the possibility that the actual physical basis of the morbid phenomena was simply not discovered cannot properly be ignored.

When a patient is actually affected with *cerebral syphilis*, the unmistakable features of the accident, as indicated above, often follow the milder symptoms. The headache, which was at first simply annoying or tolerable, sets in with paroxysms of distress which make the patient dread the hours of the night as a period of torture. Constant or intermittent grinding, boring, or hammering sensations are referred to the whole or any one of the regions of the head described above. The patient becomes eloquent in declaring that the head feels as if it were screwed in a vice, riveted with iron bands, hammered upon an anvil, etc. Under treatment even this condition may yield in a few days, or, defying all skill (a rare complication), go on to the extreme conditions described later. At times definitely circumscribed regions of tenderness may be appreciated by both patient and physician, the latter by the pain evoked in percussion of the cranial vault. Insomnia, vertigo, intellectual hebetude, apathy, melancholia, and other morbid mental states, photophobia, and marked cachexia are the usual concomitants of this state. When the disorder progresses uninterruptedly to full evolution, the patient becomes weaker, takes to the bed day and night, may exhibit some mild ataxic or paretic symptoms, usually goes into delirium, and presents the picture of one affected with utterly hopeless cerebral disease. Yet here, as so often in the history of this singular malady, he is really far from such a hopeless state, and thus furnishes the diagnostician with a clew to the syphilitic origin of the disease. Such a patient, properly treated, may rise from his bed, regain his flesh, return to his occupation, and live out his natural days, so far as regards the disorder under consideration.

Many odd features may be presented in the course of this complication. There are patients thus affected who present singular hallucinations; yet others suffer from vague terrors, dreading self-destruction or attacks from enemies.

Chorea, or at least choreic symptoms, may be recognized in some patients of this class. Spasmodic contractions may affect one or a group of muscles, either before or after the occurrence of paralytic symptoms, or independently of the latter. There may be slight, severe, transitory, remittent, or constant contractions of muscles of the head or extremities. A persistent, rhythmical swaying of the head from side to side may last during the hours of wakefulness for a fortnight.

Aphasia, partial or complete, continuous or intermittent, often of sudden onset, may be the sole symptom of nervous syphilis, or occur before or after some of its grave complications.

Paralysis, sensory or motor, partial or complete, usually succeeds a prodromal stage in which the patient has complained of obstinately persistent headache or some other premonitory symptom of cerebral disorder. The paralyses of the motor muscles of the eye belonging to this group of disorders have been already described. In a similar way the nerves of special sense, not only those of vision and hearing, but also those of olfaction and gustation, are totally or partially deprived of sensitiveness to external impressions.

Hemiplegia, occurring suddenly in a patient under fifty years of age, is, in the great majority of all cases, of syphilitic origin. It may be of early or late, sudden or gradual occurrence, and constitute a mere paresis of a group of muscles on one side, or, much more rarely, a complete motor paralysis of one-half of the body. It is usually preceded by cephalalgia, vertigo, lassitude, and neuralgia, with anæsthesia or tingling of the parts about to be affected, or mild choreic, rarely convulsive, seizures. Usually, after well-marked prodromal symptoms have been exhibited for some days or weeks, the patient awakes from sleep to find himself more or less unable to move one or both limbs of one side; or the attack comes on in the hours of the day, the patient falling to the ground in a state of partial unconsciousness. The leg only is most commonly affected; at times it is followed by involvement of the arm. Rarely the arm alone is affected. The bladder and rectum may participate in the resulting symptoms by loss of power to expel their contents. Alternate paralysis of the facial muscles is occasionally noted, *e.g.*, the right leg and the left side of the face. There may be dilatation of the pupil of the eye on the sound or affected side, with or without ptosis and involvement of the oculomotorius. With these symptoms are occasionally associated total genital impotence, which may even survive the paralytic symptoms in the extremities, muscular tremors, and contractures. Sensory disturbances are few; rarely there is complete sensorimotor loss. The affection is commonly attributed to an obliterating endarteritis. The prognosis in most cases is favorable as respects the preservation of life, but restoration of the function of the paralyzed organ is rarely complete.

Epilepsy is simulated in syphilis, under the influence of which epileptiform seizures occur. They are far rarer than hemiplegic complications. With or without premonitory sensations comparable to those experienced in the aura, both the *grand mal* and *petit mal* are represented in syphilitic seizures. There is, in the first case, the usual precursory severe cephalalgia, followed by distressing sensations in the extremities or about the heart, or singular creeping sensations of chilliness. Jullien insists that during these attacks the patient, even if unable to speak or to move, never wholly loses consciousness and never utters the cry, an important diagnostic distinction.

The patient may fall as if shot, and exhibit tonic, followed by clonic, convulsions during a portion of the time, but rarely throughout the whole period occupied by a seizure. These convulsive movements do not notably affect all of the muscles of the body. The patient may foam at the mouth and bite the tongue or lips, though often, with marked convulsive seizures, these symptoms are absent. The intervals between these crises may be but a few hours, or days, or several weeks. They tend to multiply with each recurrence, and may result in dementia.

The *petit mal*, or mild form, is betrayed in tremors, spasms of the muscles, for example, of a single limb, or of the neck, or of one shoulder; dyspnœa, dysphagia, or vertigo. Other patients experience sudden loss of memory, or imperception of environment, confusion of ideation, and incoherence of speech.

Paraplegia is, in more than fifty per cent. of all cases occurring in male patients under forty years of age, of syphilitic origin. Over ninety per cent. of cases of syphilitic paraplegia occur in males. There may be precedent cephalalgia of extreme violence, rachialgia, neuralgia, convulsive seizures of the muscles of the lower extremities, and hyperæsthesia or anæsthesia of the cutaneous surface. The paraplegia may be partial or complete, and sudden or gradual as to occurrence, but, as Althaus indicates, is unaccompanied by loss of consciousness, the patient often "assisting" at the invasion. It is apt to terminate in complete loss of power of both lower extremities, with and without sensory disturbances, partial paralysis of rectum and bladder, and complete impotence, lasting often for years. One side of the body may be involved after the other; or the same side may be again affected after an interval of months has elapsed. Paralysis of cranial nerves, mental hebetude, mydriasis, and other signs of syphilis of the nervous system may be present, but are often absent; and when the paraplegia is complete this may be the sole objective symptom of the infective disease.

Tabes is an affection the precise etiological relations of which have been the subject of no little careful study and discussion. By Fournier the disorder is classed with a group of morbid conditions named by him the "parasyphilitic affections." It is now fairly well established that between seventy-five and eighty per cent. of cases of locomotor ataxia occurs in syphilitic subjects, chiefly male patients; and the symptomatology, pathology, diagnosis, and prognosis of this affection, as detailed in the treatises devoted to the subject, belong to the domain of syphilis. None the less it is to be admitted that, in the minority of cases represented by the percentages given above, the disease occurs with classical features in persons who have never contracted syphilis; and further that, as in the other affections of the group described as "parasyphilitic," there is little if any amenability to antisyphilitic treatment. In the syphilitic affections of the cord, the well-defined sclerosis of the posterior columns which is characteristic of progressive spinal ataxia is not readily recognized.

Syphilis rarely selects a definitely limited portion of the cord for its manifestations, but involves here and there a patch in the columns, near which can commonly be recognized altered vessels or investing membranes where the morbid process originated.

General paralysis of the insane ("*Délire des grandeurs*") is to-day by most modern authors placed in the category of affections described by Fournier as "parasyphilitic." It occurs in the victims of former syphilis, in almost the same proportion as does tabes; and, like that disorder, is singularly uninfluenced by antisyphilitic treatment. Due weight can be given to the argument that these are "parasyphilitic" rather than syphilitic disorders (by reason of their admitted failure to respond to energetic treatment of a syphilitic involvement) when attention is drawn to the significant fact that a group of other admittedly syphilitic changes are to the same slight degree influenced by an appropriate therapy; as for example, the pigmentary syphiloderm, monolateral mydriasis, hemianopsia, etc., all syphilitic in origin.

Jullien calls attention to the fact that the syphilitic patient supposed to have general paralysis is really ill (cachectic, anæmic, or adynamic), while the "real fool," on the contrary, exhibiting moral decrepitude, stupid facial expression, and perturbed cerebration, appears to be otherwise in good physical health. The former, moreover, is apt to display one or more of the syphilitic paralyses following a characteristic vertigo, hemicrania, or a cephalalgia, or some one of the ocular or aural complications of syphilis, in brief, at capriciously selected points where nervous symptoms are displayed. This also is associated with a milder exaltation of ideas and a more rapid evolution of symptoms.

Other symptoms of nervous syphilis are exhibited in gastro-intestinal derangements (vomiting, etc.), in functional disturbances of the kidneys and bladder, and in disorders of other viscera.

Coma, preceded by cephalalgia, anæsthesia, mental hebetude, or aphasic symptoms, may occur during sleep or result from sudden diurnal accidents. The patient is usually found lying listless, or apparently asleep, pallid, expressionless, and not suffering pain. He may be roused to take food or drink, to thrust out the tongue, or even momentarily to recognize a friend or answer a question. The pupils are usually contracted, insensitive to the light, and covered by the lids. The globes are shrunken in the orbits. Sensibility and reflex excitability are either wholly preserved, impaired, or lost. The pulse and respiration are retarded in frequency, the temperature is subnormal, and the excretions are passed unconsciously.

The pathology of these several complications of syphilis is explained chiefly in post-mortem examinations.

The cranial and other bones, when involved in an ostitis or periostitis (diffuse, circumscribed, gummatous), may produce nodes capable of explaining etiologically several of the groups of symptoms described above by pressure effects, including inflammation and even destruction of the parts invaded. Nodes of the internal tables of the cranial vault or of the vertebræ may thus be responsible for mental, paretic, paralytic, convulsive, neuralgic, and ataxic symptoms of the most varied character. Well-defined cranial nodes in the outer table also of the skull are, as the result of sympathetic influences, capable of producing many of the milder symptoms of nervous syphilis.

The meninges of the brain (dura mater, arachnoid, pia mater) are subject to the same involvement. They may be changed by pressure of a node, and be agglutinated to it; or may be separately involved in diffuse or circumscribed, single or multiple thickenings, due to proliferation and vascularization of the tissues (pachymeningitis). The lesions may be symmetrical or asymmetrical, and involve the brain more often than the cord. These changes are capable in various degrees of producing cephalalgia; and at times a distinct area of meningeal surface may be recognized as the seat of the severe headache of syphilis, with intense nocturnal exacerbation, by pressure or percussion with the finger over a limited region of the skull—a manœuvre which decidedly increases the pain.

The brain and medulla are always involved as a sequence of changes either in the bones, meninges, or vessels in anatomical relation with those organs. The softening which results may be either of the red or white forms of *ramollissement* recognized in non-syphilitic cerebral disease. Gummata of the brain may be single, or usually multiple, occasionally exceedingly numerous, circumscribed or diffuse, superficial or deep tumors, from the size of a millet-seed to that of a small egg. They most often exist as superficial lesions in direct association with gummatous changes in the meninges. They have a well-defined yellowish or whitish cheesy centre, with a firm, sclerotic, peripheral mass set in vascularized and greatly softened nervous tissue. Evidences of simple inflammation in the brain substance, excited by the irritating presence of the neoplasm, are usually to be recognized, and are described by Jullien as distinctive marks of a cerebral syphiloma, inasmuch as the brain substance tolerates with greater ease the softer nodules of tuberculosis. The deep-set lesions are much rarer, but are recognized, for example, in the substance of one ventricle, in the optic thalamus, the corpus striatum, or the white substance of the cord.

The arterial changes, responsible for so many of the nervous complications of syphilis, are of frequent occurrence, and may be primary or consecutive in order—that is, they may be the original and immediate cause of cerebral disease or the sequence of changes induced by a neighboring gumma or pachymeningitis. Heubner, Greenfield, Hutchinson, Dowse, Dreschfeld, and others have chiefly contributed to the present knowledge of this interesting subject. The small arteries are most often attacked, symmetrically at times as regards the two halves of the brain, in distinctly limited areas, where whitish points or nodules become visible to the naked eye. Longitudinal section of vessels thus implicated reveals an obliteration wholly or in part of the lumen of the vascular tube, due to thickening of the inner coat; the middle, clearly defined, being scarcely affected (endarteritis obliterans). The adventitia is doubled or trebled in volume, its cells under the microscope being exhibited as long, parallel, fusiform elements. The obliteration of the lumen, however, is chiefly due to a cellular proliferation between the endothelial lining of the vessel and the fenestrated membrane, resembling a granuloma in appearance. Externally and internally are flattened or fusiform cells, arranged more or less regularly in parallel lines, between which are more irregularly and loosely packed larger cells, mingled with minute fibres of elastic tissue and the vasa vasorum. The endothelium is then finally separated from the membrana fenestrata, and projects into the lumen of the vessel as a vegetation, occasionally forming a second fenestrated membrane on the sides of the vessel wall. In this way complete stenosis of the tube is eventually produced—an accident rare in atheroma, in which the cellular proliferation is more indolent, more generalized, more disposed to terminate by calcification, and never results in complete obliteration. These accidents are often the causes of the severe headache, vertigo, chorea, epilepsy, and other of the nervous phenomena noted above.

It is by the production of thrombosis or cerebral ischæmia that the arterial stenosis operates to induce the derangement.

A syphilitic periarteritis is described by a few authors (Charcot, Rabot, Bumstead and Taylor), in which circumscribed, lenticular, whitish masses of irregular shape result from an endarteritis affecting the external coats of the vessel, with proliferation also of the media and internal coat. The internal elastic tissue is reported intact, with round-celled infiltration of the muscular layer, and multiplication and dilatation of the vasa vasorum.

The cerebro-spinal nerves may suffer compression by an osseous or meningeal lesion of syphilis sufficient to produce a series of symptoms ranging from formication, hyperæsthesia, and moderate numbness to complete anæsthesia, analgesia (rare), or paralysis. The derangements of vision induced by syphilitic changes in the optic nerves supplying the muscles that move the globe of the eye have been already considered. In a similar way, the olfactory, sympathetic, and other nerves may be implicated. Petrow, in the cases examined by him in which the sympathetic nervous trunks were involved, recognized a pigmentation of the cellular protoplasm, attributed to the deposit of hæmatin in the nervous cells. The endothelial elements were proliferating and surrounded by polygonal nucleated cells, some undergoing colloid metamorphosis. These nervous elements were compressed by an hyperplastic connective-tissue growth, undergoing later sclerosis, and eventually starving the nervous elements into atrophy. The membranous envelope of the latter, after undergoing hypertrophy, may be the seat of fatty metamorphosis.

The treatment of the nervous complications of syphilis is that of the disease in general. The credit of employing large and progressively larger doses of the iodide of potassium in all serious emergencies, with brilliant results, is largely due to American practitioners. The best and simplest way of attaining the end is to administer drop doses of a saturated aqueous solution of the potassic or sodic iodide in a gobletful of water or milk every four hours, beginning with a relatively small dose, five to ten drops (0.33–0.66), and pushing on by increasing one drop each dose until the end in view is reached. By this means one ounce and a half (48.00) of the iodide may be given in twenty-four hours, with happy effect; and still larger doses have been reached by others. The pepsin, pancreatin, or takadiastase solutions may be employed at times with great advantage as vehicles for the administration of the salt. The rule should be to stop the increase at once on the supervention of any toxic effects or marked symptoms of physical protest against the large dose; to then hold at a given point, or to reduce the dose to a point of complete toleration, and to recognize the fact that after the extreme point of toleration has been fully reached, perhaps slightly surpassed, and for a moderate length of time held, further medication of this sort, in the absence of the definite and brilliant results usually attained by its adoption, is useless and in cases harmful. In the absence of such desired results, mercury in full doses (*e.g.*, calomel gr. $\frac{1}{10}$ [0.0066] every hour or two in any serious emergency) may prove of inestimable value.

The prognosis in syphilis of the nervous system, even in the face of apparently desperate peril, is far more favorable than in the case of nervous symptoms of similar import occurring in those who are not the victims of that disease.

Muscles, Tendons, and Articulations.—Muscular contracture is described by a number of authors as a syphilitic accident occurring slowly or rapidly, and producing fixed flexion or extension of any movable part to which the tendon of the muscle is attached, the latter, on palpation, being recognized as a rigid and inflexible cord. The joints are not in such cases involved. One or several muscles may be attacked, the biceps being that most commonly affected, the forearm being then flexed at an acute angle upon the arm. The involved muscle may and may not be then the seat of pain and tenderness. A tetaniform involvement also of a much larger number of muscles is described as of occurrence in syphilis.

In the diffuse form of myositis occurring in syphilis, there is diffuse swelling of the whole or a part of a muscle, some redness and œdema of the overlying skin, and pain when the muscular fibres contract. Gummata of the muscles are small, at first firm, later softish, usually globular masses, from the size of a nut to that of an egg, of insidious development, and often, when in process of disintegration, attached to the skin and undergoing the cycle of changes already described in connection with the ulcer resulting from subcutaneous gummata. It is believed that the sheaths of the muscle-bundles are first involved in these changes. They undergo, in some instances, osseous and cartilaginous metamorphoses instead of disintegrating.

The tendons, tendinous sheaths, and aponeuroses may become in syphilis the seat of flattish, triangular, circumscribed, and usually painless tumors, due to effusion in the serous sacs; or to projecting gummata which may break down and ulcerate, leaving a cicatrix the contracture of which may subsequently interfere with the function of the muscle to which such a tendon or aponeurosis is attached. Diffuse gummatous thickenings also affect the fasciæ and aponeuroses, more particularly those of the lower extremities.

In gummatous syphilis the bursæ are not rarely affected, more particularly those of the patella and of the tibial tuberosity. They begin as single, painless or slightly painful, firm, elastic, or softish gummata, from the size of a nut to that of an egg, which are apt to involve the skin eventually, and to be obstinate under treatment.

Syphilitic rheumatism (arthralgia, pseudo rheumatism) may be an acute, more often a subacute, polyarthritis with tender and painful points about the articulations, preceded often for days by arthritic pains, as distinguished from simple rheumatism. This complication is remarkable for the failure of acuity in the symptoms, the relative painlessness of the affected joints, the absence of articular swellings (*arthritis sine materia*), and the nocturnal exacerbation of the pain. Hydrarthrosis, most commonly symmetrical and of the knee joints, though also mono-articular, is both an early and a late symptom of syphilis, and is chiefly remarkable for the extent to which the joints may be distended with synovial fluid, and be yet sufficiently free from pain to permit of performance of their function. It often recurs and disappears for several weeks at a time. The so-called "syphilitic white swelling" is due to fibrous thickenings and subsynovial, gummatous infiltrations in and about the joint. These synovial effusions chiefly occur in the subjects of cachexia, or male patients of fragile constitution.

The fingers and toes may be the seat of early and late syphilitic lesions, and in both acquired and inherited syphilis. To Dr. R. W. Taylor's researches we are indebted for a knowledge of this interesting subject, to which merely a brief reference can be made in these pages.

The affection is more common in hereditary than in acquired disease. In the former the disease may begin in the subcutaneous connective and fibrous articular tissues, or primarily in the osseous and periosteal tissues, and consecutively invade the other structures named. The digit affected, either in one or in several phalanges, enlarges insidiously, becomes dense, painful, inflexible, with attached overlying and purplish-red skin. Sometimes an articular hydrarthrosis can be detected; again, one or more of the symptoms resulting from gummatous infiltration. These gummatous deposit. are circumscribed or diffuse, and not prone to ulcerative degeneration. Specific dactylitic osteomyelitis, periostitis, or osteoperiostitis may be a slow, rapid, or relapsing accident, producing in full evolution a balloon- or acorn-shaped, globular, or pyrform swelling, involving one or several phalanges of a single digit, usually the proximal, and more often those of the fingers than of the toes. As sequelæ, may be enumerated inflammatory changes with abscesses discharging a caseous matter, crepitation from roughness of the articular faces of the cartilages, the formation of sinuses, hydrarthrosis, and osseous atrophy after resorption of the gummatous deposit, leaving the shaft of the phalanx more slender and fragile than before. In other yet more marked cases the phalanx is reduced by shrinkage till the finger is shortened one-third or one-fourth of its length. The resulting deformity is conspicuous, and almost peculiar to the special disease under consideration.

Cartilages and bones are attacked in both early and late forms of the disease. The most common form of bone disease is an osteoperiostitis characterized by inflammatory phenomena, vascularization, and exudation, diffuse or circumscribed, of the area of contact of the osseous and periosteal surfaces. The result is declared in the formation of well-defined, rarely poorly circumscribed nodosities in various degrees sensitive, and usually the seat of a characteristic pain, intensely, often intolerably, aggravated at night after retiring to bed. Absorption may result or, much more rarely, degeneration and exfoliation of a thin lamella of bone. In other cases an exostosis results from a plastic effusion between the periosteum and bone, usually circumscribed and flattish, globoid, annular, sessile, or pedunculated, which may undergo eburnation and exhibit compact or cancellated tissue in its structure. When the bone has been infiltrated with a gummatous material which degenerates, it is usually the epiphysis which is the seat of the disorder, though the medulla (osteomyelitis) and bony substance, or even periosteum and bone, may be involved. Ulceration may then leave a roundish cavity, from the size of a pea to that of a nut, possibly communicating with the medullary canal, filled with a bright yellowish pulp; the faces of the cartilages become the seat of salient granulations and depressions (scars?), the size of millet-seeds. At times the diaphysis of the bone is first attacked and the epiphysis secondarily. Often the synovial membrane remains intact.

The "dry caries" or "inflammatory atrophy" of Virchow is a change beginning with vascularization, but unaccompanied by suppuration or ulceration, in which the osseous substance is found wanting in stellate or foveolated pits which may enlarge in the line of furrows representing the Haversian canals. These parts are surrounded by hyperostosis. These and similar depressions in the osseous substances, when osteoid growth has ceased centrally and is actively progressing at the periphery, may be regarded as syphilitic cicatrices of bone. The meninges, periosteum, and integument may participate in the formation of such cicatrices, resulting finally in the production of a uniform, thin, contractured, whitish or grayish fibrous tissue, unprovided with vessels.

The various bones of the skeleton are in different degrees subject to the several changes described above. The vault of the cranium is particularly liable, in both external and internal tables, to exhibit single or multiple, circumscribed osseous changes, as also are the sternum, the clavicle, the ribs, and particularly the tibiæ. The substernal and similar pains, noted so frequently as precocious phenomena in the early periods of the disease, are probably associated with transitory osteoperiosteal hyperæmia. In the later periods the nodes that form, whether inflammatory or gummatous in type, are characterized by the same severe nocturnal exaggeration of the pain they excite and by marked localized tenderness. Some of the consequences resulting from the pressure induced by intracranial nodes have been described in the paragraphs devoted to the phenomena of nervous syphilis. Gummata of the frontal and temporal bones, forming firm projecting tumors, are at times so conspicuous as to produce marked deformity. Other bones besides those named, *e.g.*, the radius, ulna, femur, maxillary, and, indeed, any part of the skeleton, may become the seat of these lesions. The treatment is that of syphilis in general, more particularly in its advanced stage. The remarkable effect of the potassic iodide upon many of these lesions is one of the demonstrations, which even the most sceptical are compelled to accept, of the signal efficacy of an ingested drug upon a neoplasm defying local therapy. The dose is to be pushed, to secure marked relief, to any required point precisely as indicated above in the management of nervous symptoms. Indeed, as will be gathered from what has preceded, the same treatment is often urgently demanded in the same patient, at the same moment, for relief of grave nervous complications depending solely upon syphilitic osseous disease. Locally, the mercurial ointments, plasters, and oleates, with occasional use of anodynes, fill an important part.

HEREDITARY SYPHILIS.—This form of the disease, the only one not known to originate by an initial sclerosis, is also termed congenital and infantile syphilis. The syphilis of infants, acquired by accidental or intentional transmission after birth, is practically that of acquired syphilis of adults, the differences being chiefly due to the tender skin of the young patient and its extreme liability to nutritional disorders.

Hereditary syphilis is the disease transmitted by inheritance from one or both progenitors to a second generation. Evidences of such transmission to the third generation are extremely rare. The more active the disease in the progenitors, the greater the chances of infection of the offspring.

In inherited, no less than in acquired, syphilis pathologists have recognized micro-organisms which have been claimed to be effective in the evolution of the disease. Doutrelepont, Kassowitz, Hochsinger, Kalisko, and Chatzen have both detected and failed to detect streptococci in the viscera of children affected with hereditary lues, as also in the skin, mucous surfaces, bones, and liver. In some instances the lymph-channels have been found choked with micro organisms of this kind, which fact has suggested to Chatzen that the cachexia of some patients in this category was a streptococcic septicæmia.

Relative Influence of the Parents in the Transmission of the Disease.—The father alone, when the victim of active constitutional syphilis, is capable of transmitting the disease to his child without infection of the mother. It is probable that he does not possess this power before the disease is actively displayed in his own person by constitutional symptoms. It is certain that this power is greatly weakened while he is under the influence of mercury; is weakened and regained during the respective periods of repose and activity so commonly observed in the disease; and is finally extinguished by time. It remains to be admitted that the cases in which the father alone is thus responsible for syphilis in the second generation are far fewer than those in which the mother alone is thus responsible; and that the power of such transmissibility is positively denied to the father by the followers of Cullerier, Oewre, and others.

The mother alone, the father being unaffected, may transmit syphilis to the child, if she be the victim of active constitutional disease. If conception occur later than the twentieth day after the appearance of the earliest syphiloderm, the product of such conception is almost certainly doomed to destruction, abortion of the ovum commonly following from the third to the seventh month. The woman, however profoundly syphilitic, may abort or miscarry in consequence of the cachectic state to which she is reduced by syphilis, and may thus throw off, as in any cachectic condition, the unaffected germ. Again, the child may escape entirely by the operation of that inscrutable law which ever and again protects the offspring from the vices and errors of the parents. Lastly, in a series of pregnancies, abortions may be followed by miscarriages; the latter by stillbirths at term; then by viable infants exhibiting symptoms of syphilis before the fourth month of life; and, lastly, by the birth of children in whom syphilis can never be recognized, the power of transmission being weakened till it is wholly lost in the process of time.

If the mother be affected after conception, it is possible that she cannot convey her disease to the child. She may abort or miscarry in consequence of the anæmia induced by her own disease, but it is improbable that, either in the first or latter half of pregnancy (both periods have been claimed as those of special danger), the virus can be transmitted through the utero-placental circulation. Cases have been cited in support of both views as to the possibility and impossibility of such transmission, the cases cited in support of the affirmative view being in the main defective, by reason of failure to demonstrate both perfect immunity of the father and positive syphilis of the child.

A healthy mother may bear a syphilitic child. On this point also there has been much division of authority. The larger number of all mothers who bear syphilitic children are themselves unquestionably syphilitic. But the possibility that a syphilitic child may be infected by inheritance from the father alone, the mother remaining sound (precisely as is the case when the child is sound and the mother infected), is demonstrated by numerous records. In this country the facts set forth abroad by Kassowitz and others have been substantiated by reported cases. The well-known law of Colles is urged in support of such transmission. That law formulates a well-known clinical fact, viz., that the mother of a syphilitic child is never infected at the breast by her offspring—the secretions of whose diseased mouth are infective for all healthy persons. A few exceptions are reported to this law, so few and so inconclusive as rather more fully to establish its general applicability. It is probable that the system of the mother, after the bearing of such children, is so modified as to render her incapable of receiving the disease. If the sound child be infected at the moment of birth by direct contact with recently developed, secreting lesions existing upon any part of the external genitals of the mother (an accident reported in a few cases), the result is acquired infantile, and not inherited, syphilis.

The clinical symptoms of hereditary syphilis are first the death of ovum or fœtus. These products of conception are then ushered into the world either undistinguishable from the dead products of pregnancies where no syphilis has interfered; or macerated, the epidermis being readily separable from the corium, which is deeply congested, or, for the reason first named, raised into bullæ, and the viscera in various ways are profoundly altered. In a second list are to be classed still-births, and the birth of children surviving but a brief time. These may be apparently unaffected by disease; or covered, in various degrees, with bullous lesions produced by passive exudation of fluids elevating the loosened epidermis from the corium; or they suffer from visceral changes. In a third category may be named children who survive for various periods to maturity. One-third of all are thought, however, to perish without attaining that development. Many perish before the second month; those who survive commonly exhibit the symptoms of inherited syphilis in the same period, even if no signs are apparent at birth. Hereditary syphilis is rarely deferred in its manifestations after the fourth month. Cases reported as of late inherited syphilis, where the first symptoms of that disease were manifested at the period of puberty, for example, are regarded by most experts with suspicion.

The placenta may be the seat of a diffuse or circumscribed gummatous infiltration. The two may concur. In such cases the syphiloma is characterized as usual by the firm, external, fibrous, grayish-tinted layers surrounding a softer, yellowish central mass. Hydramnios is also counted among the possible syphilitic changes of pregnancy.

The skin of the victim of inherited syphilis is subject to many changes, resembling, for the most part, those recognized in the acquired form of the disease. It is commonly seen to be either flaccid and wrinkled, or tightly stretched over the bones as if deprived of its panniculus adiposus. In this way the characteristic little-old-man and little-old-woman appearance of the syphilitic infant is produced. The skin has, moreover, a not less constant and characteristic sallow, yellowish, earthy hue. Manifestly the nutrition is profoundly impaired, and the child exhibits a series of symptoms, such as vomiting, diarrhœa, etc., which indicate that not the skin alone but other organs are participating in the disease. As a matter of practical moment, it is well for the practitioner to remember that a healthy-looking, well-nourished child, six months and more of age, without pulmonary or gastro-intestinal disorder and no signs of disease save a suspicious-looking eruption upon the skin, is probably *not* the victim of inherited syphilis.

The macular or erythematous rash (roseola) appears usually over the belly, face, neck, palms, extremities, and other parts, in the form of roundish or oval-shaped macules, from the size of a split pea to that of a finger nail, of characteristic copper-and-reddish shade, soon refusing to yield under pressure, often seen as the earliest cutaneous symptom of the disease. The spots may enlarge by multiplication or coalescence; may, in cases, become elevated or covered with scales; or may undergo fissure.

Papules, mucous plaques, mucous patches (of the skin and mucous membranes), and condylomata lata are all phases of one and the same process of proliferation in hereditary syphilis. The most common of all is the occurrence of flattened papules or patches in the nasal cavity, furnishing a serous discharge which rapidly becomes purulent or hemorrhagic in type, and which by desiccation soon blocks up with crusts the nasal passages. As a consequence a characteristic "snuffles" follows, the child abandoning the nipple to get breath, and even in sleep respiring with a suspicious snore. Specific coryzas of this sort may progress to ulceration or osseous necrosis. Similar roundish or oval-shaped patches, or (after confluence) large sheets of involved mucous surface, may be recognized in the mouth, furnishing a highly contagious secretion. In this way the tongue, lips, gums, and fauces may be involved, and the child may be rendered incapable of seizing the nipple with the mouth. At the angles of the mouth, also, on the muco-cutaneous surface, flat papules, condylomata, or secreting patches may conceal the natural outlines of the parts, be extensively crust-covered, or even superficially or deeply ulcerated.

Over the general surface of the body, small or large, flat or, more rarely, acuminate papules, copper-colored and reddish in hue, smooth or scaling, symmetrical, and generalized or limited to a single region, may be conspicuous. They may coalesce, furnish a patch of infiltration, and even extensively ulcerate. The most frequent manifestations of this type, next to the nasal lesions accompanied by "snuffles," are the condylomata about the anus, from the size of a pea to that of an egg and larger, flattened, whitish or reddish lesions, secreting, elevated, and distinctly circumscribed.

Vesicles, isolated or confluent, conical or flattened, from the size of a pinhead to that of a split pea, may also spring from macules or papules, rest upon a brownish and reddish base, and be filled with serum or a seropurulent fluid. They are rare lesions. Pustules, from the size of a pinhead to that of a split pea, are more often seen, with and without a previous or concurrent evolution of vesicles or papules; often as a metamorphosis of the latter. The skin thus affected is commonly infiltrated, purplish, and covered with brownish or greenish crusts. Beneath these may be simply excoriation or ulceration. The genital region, face, scalp, and lower extremities may be involved; rarely the entire surface of the body. The scarring which results is not conspicuous.

Bullæ are grave and unfortunately common symptoms of inherited syphilis. They may, as indicated above, be conspicuous at birth, single or multiple as to number; or develop later as wine-colored, circumscribed patches of integument; first pea-sized, later as large as an egg, an orange, or a cocoanut, filled with serous, lactescent, or hemorrhagic contents. The palms and soles are frequently involved. The areola is violaceous, often infiltrated and raised. The brownish crusts cover ulcers with a foul, hemorrhagic, or diphtheritic floor. Death usually ensues, when the eruption is at all generalized, in the course of a few days. Furuncles beginning as circumscribed cutaneous or subcutaneous and indolent nodules, from the size of a pea to that of a nut, may be in some cases so numerous as to constitute a characteristic and even symmetrical eruption. They may, after a typical suppuration, discharge a core by sloughing, or break down into conical ulcers of crateriform shape.

Tubercles and gummata may observe almost the same cycle. They also begin as roundish or irregularly knobbed, usually subcutaneous nodules, which break down, furnish an irritating, semipurulent, or serous discharge, and finally result in ulcers of the typical aspect already described as of occurrence in the acquired forms of syphilis. These ulcers may also follow the less circumscribed gummatous infiltrations of the skin and subcutaneous tissues.

Many of the grave cases resulting in profound destruction of tissue about the face (eyes, nose, lips, jaws, etc.), illustrated in the works of the best authors on the subject of hereditary syphilis, originate in gummata, the ulcerative processes in or beneath the skin, spreading thence to muscles, fascia, periosteum, and bone.

The *larynx, trachea,* and *neighboring parts* may be, in early inherited disease, the seat of ulcerations resulting in the production of stenosis, cicatrization, and bridles stretched between adjacent walls, so as to interfere with the function of the organ implicated. The late forms are described by Fournier as diffuse hyperplastic, circumscribed gummatous, and sclero-gummatous—the last named a combination of other forms. These may be serious in consequence of the results recognized in acquired disease, viz., production of (chiefly laryngeal) dyspnœa, glottic spasm, acute œdema, and sudden death. Sclerosed masses, subsequently exhibiting a central yellowish softening, have been recognized by Lebert and others in the lungs of children dead of inherited syphilis. These are believed to be gummata.

The mucous lining of the *alimentary canal* may be the seat of changes similar to those observed in the exposed mucous surfaces of the subjects of the disease. Circumscribed hyperæmia and even indurated hyperplastic, as well as ulcerative, patches have been recognized about the solitary and agminated glands. The liver may be, after the occurrence of specific changes in the walls of its vessels, hypertrophied, dense, and resisting; or the seat of pedunculated tumors, or of diffuse or circumscribed parenchymatous gummata. These may be miliary or nut-sized, and surrounded by the usual fibroplastic envelope. The spleen is probably always involved in the child affected with inherited syphilis. It may be the seat of a partial or general perisplenitis, capsular or subcapsular in situation; is always greatly increased in size and weight; and may undergo later, under treatment, reduction to its normal size, or, in other cases, lardaceous metamorphosis. The increase in size and weight which has been noticed in the pancreas is different, in that it seems to be accompanied by a sclerosis due to hypertrophy of the interstitial connective tissue.

The *suprarenal capsules* may be involved in a partial or complete pericapsulitis, as also in a parenchymatous deposit of miliary gummata. Fatty, colloid, and gelatiniform degeneration may be observed as a result of these morbid changes in both capsule and substance proper. The *kidney* has been found enlarged and also containing one or many miliary, whitish or yellowish, circumscribed gummata, or diffuse infiltrations. The origin of these lesions has been traced to proliferative changes in the connective-tissue stroma of the organ. Here, too, colloid and fatty degeneration has ensued—in rare cases, ulcerative destruction. More often than is generally taught there is serious involvement of one or both *testes* in male patients, the disorder beginning with an indolent tumefaction of the testis proper (the epididymis being usually spared), smooth, lobulated, and accompanied or not by moderate hydrocele and scrotal engorgement. Fournier calls attention to the discovery, in patients exhibiting tardy symptoms of inherited disease, of small, densely indurated testicles, either arrested in development or the fruit of the gummatous changes wrought in earlier periods of the disease. It is possible that the ovaries may be similarly involved (Panot).

The *hair* and *nails* are affected in hereditary as in acquired syphilis, chiefly after involvement of the tissues on which they depend for nutrition and support. In this way patches of alopecia become visible in the scalp. The nails are surrounded by a ring of purplish infiltration, or papulo-pustules, degenerating into ulcers, undermine the matrix and possibly finish with loss of the nail and formation of a cicatrix. The deformity of the distal phalanx in these cases is strikingly characteristic, presenting as it does a livid club-like enlargement, often both tender and painful, bearing, usually on one side only, a semilunar ulcer with sero-purulent secretion, foul base, and distorted or displaced nail. The nail-substance in these cases may be friable, eroded, "worm-eaten" in appearance, frayed, or laterally ridged and furrowed.

The changes so strikingly characteristic of inherited syphilis in the *eye* (keratitis, etc.), *ear* (remediless deafness of late inherited syphilis), and *teeth* (Hutchinson's changes) have already been described. A group of symptoms less classical and constant are puriform dépôts in the *thymus gland*, supposed to be abscesses (Dubois); glandular abscesses due to the irritation of neighboring cutaneous lesions (*e.g.*, in the neck, when associated with scalp or mouth disease); hæmophilia, or hemorrhagic symptoms appreciable at birth or soon after, in the cutaneous or mucous surfaces, probably due in greater measure to the cachexia of the disease than to specific changes; stenosis of veins and arteries (perhaps associated with gummatous changes in the vascular wall similar to those occurring in the endarteritis obliterans of acquired syphilis); and fusiform swellings of the synovial sheaths over the metacarpal bones.

The affections of the *bones* in hereditary syphilis have been exhaustively studied by Wegner, Waldeyer, Parrot, Taylor, Fournier, and others. They are among the most common of all the symptoms of the disease, being next in order to the ocular changes. Many of the phenomena long ascribed to rickets are to-day referred to inherited syphilis. Osteochondritis usually affects the diaphyso-epiphyseal extremity of the forearm, leg, arm, or thigh, but all the bones may be involved in the newly born infant, and this as the sole manifestation of the disease, or in conjunction with skin and other lesions. A partial or complete annular swelling, smooth, irregular, or ridged, is then found, of insidious or rapid development, encircling the extremity of the bone (distal extremity of ulna, sternal extremity of clavicle). There may be articular effusions in the contiguous joint. The swelling may disappear under treatment, or degenerate by ulceration as in gummata, resulting in loosening, separation, or destruction of the epiphysis or cartilage; or ultimately result in death by exhaustion. The bone may be shortened as a result, or invested with a thickened periosteum. The pathological changes may be described briefly as due to proliferation of the cartilage cells, with mamelonation of the epiphyseal surface and calcification of the osteoid processes. Periosteal and perichondrial thickenings follow, conjointly with retarded osteogenesis at some points.

Osteoperiostitis is a later bone-symptom of inherited syphilis, affecting predominantly the tibia, but also the ulna, radius, cranial, and other bones, often more than one bone in one subject of the disease, and then at times symmetrically. The hyperostosis resulting may distort the tibia so as to produce the so-called "sabre-blade" deformity, its voluminous mass forming a curve, with an anterior or lateral convexity, painful, tender, and indolent of development; or it may result in characteristic multiple cranial hyperostoses of the temporal and frontal regions. All these forms may result in necrosis, ulceration of bone, and formation of fistulous tracts through which sequestra may be removed.

In gummatous osteomyelitis the medullary canal, after degeneration of a gummatous infiltration, may be the seat of a cheesy tissue here and there enclosing solid masses, surrounded by layers of newly formed bone.

The syphilitic dactylitis of inherited resembles that of acquired disease, the swellings attacking sowly or rapidly, with or without pain, one or more of the proximal phalanges, or metacarpal or metatarsal bones. In all these bone-lesions the joints may participate secondarily, or the synovial membrane or fibrous capsule may be first to induce a hydrarthrosis or tumefaction, which may go on to degenerative changes involving cartilage and bone, or be averted at any stage by treatment.

The nervous system, in inherited syphilis, is chiefly involved after the occurrence of structural changes in the meninges and other neighboring parts. Fibrous and gummatous thickenings and infiltrations, diffuse and circumscribed, may implicate one or more of the meningeal layers, agglutinating them to each other or to the nervous structures they enclose. Periostitis of the surfaces in contact with these membranes, intracephalic scleroses and gummata, and occlusions of the lumen of the cerebral vessels, may here, as in acquired disease, be followed by a long series of nervous symptoms, dilatation of the pupil, facial paralysis, paraplegia, hemiplegia, epileptiform seizures, hydrocephalus, idiocy, and various grades of failure of intellectual development and vigor. Fournier, in describing the late forms of this complication, lays stress upon the occurrence of severe and persistent cephalalgias, similar to those so frequently recognized in acquired syphilis of the nervous system, as also upon the frequency of urinary incontinence. The same author believes that there is an heredito-syphilitic tabes, and possibly also a sclerosis *en plaques*. The paralyses resulting from compression or other changes in the nervous trunk chiefly involve the ocular muscles.

The *treatment* of the mother affected with syphilis, and pregnant or nursing a syphilitic infant, is usually indicated. Mercurial inunction of the infant by smearing its flannel roller with oleates and salves is an efficient means of introducing the metal when it is required. Calomel, or the gray powder, may be given, one grain to one-twentieth of either (0.066 to 0.0033) rubbed up with sugar of milk, and placed upon the tongue of the infant, three or four times daily. The dose can be nicely adjusted to the requirements of each case. The bichloride may be substituted in combination with syrup of licorice or of ginger. Ten drops may be given of a two ounce (64.0) solution, containing from one-fourth to one grain (0.0160 to 0.066) of the sublimate to the ounce (32.0). Inunction is, however, preferable for the majority of cases, with the administration of cod liver oil by the mouth. When mercury and the iodide of potassium are both indicated (more particularly in the management of osseous lesions), the several combinations known as the syrup of Gibert are useful, *e.g.*:

℞ Hydrarg. biniodid............. gr. i. (0.066)
Potass. iodid.................. ℥ ss. (16.0)
Syr. glycyrrhiz. (vel zingiber.),
Aq. dest.....................āā ℥ ij. (64.0)
M.

Of this solution the infant under the fourth month can take from five to ten drops in water, the larger dose being gradually reached. Similarly, in all portentous cases, the iodide of potassium may be administered in drop doses of a saturated solution to the point required to produce any desired effect, as already described in the treatment of acquired nervous syphilis. In all cases the diet and hygiene are highly important. The heredito-syphilitic child should be at the breast of the mother (and at the breast of none other), if it can be thus properly nourished. The local management of the mouth, of the ano-genital region, and of all syphilodermata is important, and to be conducted on principles heretofore indicated. Tonics are often useful. The prognosis is grave in all severe cases. In viable children, free from visceral complications, much can be accomplished by treatment.

TREATMENT OF SYPHILIS.—The chief point of importance in syphilis is the non-medicinal management of the patient, without a proper knowledge of which the most skilful use of drugs is ineffective. This introduces to the wide field of diet, hygiene, and occupation of mind and body. The diet should be nutritious, and should exclude alcohol in all forms not specifically directed by the practitioner, with a view to securing its valuable tonic (not stimulating) effects. Tobacco in every form is best discarded, as having an injurious effect upon the nutrition in general, as well as upon the mucous surface of the mouth, which constitutes such a fertile field for the development of mucous patches. The body should be sponged daily with cool or tepid (often with salt) water, and then briskly scrubbed until warm, when the general surface not the seat of syphilodermata permits such a course. The skin should be properly protected by warm underwear. In the case of syphilitic patients sexual indulgence should be prohibited. Most patients are better for regular and systematic attention to their usual occupation, though the latter should not unduly tax the mental or physical powers. The bowels should be evacuated daily. Exercise in the open air and due regulation of the hours of sleep should not be forgotten. In many cases, where the purse of the patient will permit, the recreation of travel, a sojourn at the seashore, or a change from an inhospitable to a mild climate, are valuable steps toward recovery.

In a small percentage of cases the expectant or tonic treatment of syphilis, conducted largely by the measures described above, aided by the use of tonics (ferruginous, bitter, acid), suffices for what seems to be a cure. Indeed, no observer of large experience can deny that cases of exceedingly mild and benignant syphilis are often untreated and exhibit no recurrence.

The immense preponderance of cases, however, is on the other side of this slender border-line of safety; and the danger of an expectant course, for most patients, is sufficiently grave to furnish the basis of serious charges against the practitioner who habitually pursues it.

Mercury is to-day, as for nearly four hundred years past, the most efficient of drugs in the treatment of syphilis. It is given by the mouth in the form of the protiodide, biniodide, bichloride, calomel, gray powder, blue mass, tannate, or other combinations of the metal. The protiodide is deservedly popular with American physicians, and may be given in one-fifth of a grain (1 cgm.) granules, pellets, or discs. It is usual to begin with one after each meal, and to increase gradually till some constitutional effect is produced, such as looseness of the bowels, slightly increased flow of saliva, or moderate abdominal pain, after which the dose is reduced. Keyes suggests at this point a "tonic" dose—one which can be tolerated for months at a time without inconvenience, and reached by the reduction of the dose described above. For speedy effect, calomel is employed in doses of one-tenth of a grain (0.0066) every hour; and for slower effect, less often. It is well administered in powder rubbed up with sugar of milk. The mercurial pill has the advantage of being readily combined with iron, as *e.g.*:

℞. Pil. hydrarg................. ℈ ij. (2.66)
Mass. Vallet (pil. ferri subcarb.) ℈ ss. (0.66)
Nux vom. ext................ gr. iv. (0.24)
M. Ft. pil., No. xx. S.: One after meals.

The dried ferric sulphate, quinine, ergotine, and aloes may each, when indicated, be incorporated in these or similar pills.

The bichloride is often best combined with iron in some such acid solution as:

℞ Hydrarg. bichlorid...gr. i.-ij. (0.066-0.133.)
Ferri tinct. mur.,
Acid. mur. dil.....āā ʒ ij.-iv. (8.0-16.)
Syr. zingiber. (vel. sarzæ)..............f ℥ ij. (32.0.)
Aq. dest............ad f ℥ vi. (192.0.)
M. S.: A teaspoonful in a glassful of water after each meal. To this the sulphate of strychnine in medicinal doses may often be advantageously added.

Solutions of the bichloride effected with the aid of alcohol or with an equal quantity of the muriate of ammonium are also useful.

The biniodide is usually administered by decomposing corrosive sublimate with the potassic iodide, and dissolving the precipitate in an excess of the same salt, *e.g.*:

℞ Hydrarg. bichlorid........... gr. i. (0.066.)
Potass. iodid.................. ʒ ij. (8.0.)
Aq. dest...................... ℥ iij. (96.0.)
M. S.: A teaspoonful in water after meals.

The Gibert formula, modified variously by almost every author, is nearly as follows:

℞ Hydrarg. biniodid.............gr. i. (0.06.)
Potass. iodid..................... ʒ i. (4 0.)
Aq. dest......................... ʒ i. (4.0.)
M. Filtra, deinde adde syrup. aurant. cort.................... ʒ vi. (192.0.)
S.: One to two teaspoonfuls in water after eating.

Combinations of mercury and the potassic iodide are employed chiefly in the so-called "mixed" treatment of syphilis; in lesions that are transitional in type between the graver and milder forms; and also in many precarious or rebellious symptoms in the earlier stages of the malady. Pills of the bichloride and biniodide are usually objectionable on account of their tendency to the production of irritative effects, but are in some cases given with advantage. From one-sixteenth to one fortieth of a grain of either (0.004 to 0.0016) may thus be administered after meals.

Mercury is of great service when applied by vapor in fumigation. This method is generally, in the larger cities of the country, relegated to the bath-houses, but by the aid of a chair, a blanket, and the Schering (formalin) lamp, it can be employed at the residence of any patient. From one to three drachms (4.0-12.0) of calomel, cinnabar, or the gray oxide, or two or more of them in combination, are used for the production of the vapor when placed on the metallic plate of the lamp. Steam is furnished by water boiling in the chamber designed for that purpose, and the naked and sweating skin of the patient wrapped in the blanket and seated over the lamp, is thus subjected two or three times a week to the fumes of the mercury.

The uncleanly, but very effective, method of introducing mercury by inunction is popular abroad, but used in this country chiefly by experts, in hospitals, and at certain Springs enjoying repute for the relief of this disorder. Equal parts of the twenty-per-cent. mercuric oleate and scented vaseline, or the ordinary mercurial ointment, made with lanolin oil, may be used, one drachm (4.0) or more being rubbed at night before retiring into different portions of the skin (selecting a new region each night), and removed by a bath in the morning.

Hypodermatic injections of mercury in various forms are popular upon the continent of Europe, but are much less frequently employed in England and America. They are rapidly effective when used. They have been the subject of much favorable and adverse criticism, and are both praised and decried by leading syphilographers. They are subject to the disadvantage of requiring a physician for the administration of each dose, and are therefore better suited to hospital than to private practice. The following formulæ have been employed: Calomel, gr. iss. to iij. (0.10 to 0.2), rubbed up with about twenty-four minims (1.5) of pure glycerin (Scarenzio); corrosive sublimate, four grains to the ounce (0.266 to 32.0) of distilled water; fifteen minims (1.00) to be injected every two or three days (Lewin). These solutions have been modified by incorporating with them one-tenth of a grain (0.0066) of the acetate or of the sulphate of morphine to relieve pain; and the chloride of sodium, four parts to one of the bichloride, to render the solution less irritating. As these subcutaneous injections are liable to be followed by abscesses, attempts have been made in the direction of securing a soluble albuminate or peptonate of mercury, all of which have proved unsatisfactory. Solutions of the bicyanide, biniodide, nitrate, and formidate of mercury have also been recommended. None of these devices has yet rivalled in popularity the solutions of corrosive sublimate in distilled water.

When mercury produces its happiest effects in syphilis, by any mode of administration, the symptoms diminish or disappear, and the patient actually gains in weight. Even when improperly employed, mercury is not (always) responsible for many of the results popularly ascribed to its influence. These are chiefly syphilitic symptoms of patients misinformed as to the nature of their disorder. The statistics collated by the physicians of the great Russian mercury mines, of disease observed among the workers in the metal, include none of the symptoms popularly ascribed to the influence of this metal in syphilitic patients—mouth-patches, rheumatism, eruptive symptoms, etc. They are all in the direction of salivation, and, in grave cases, of maxillary necrosis. Tenderness of the gums, moderate fetor of the breath, slight increase in the salivary flow, noticeable indentation of the sides of the tongue by the molar teeth, and tumefaction of the mucous membrane—these are the first signs of a toxic effect, which may increase, if the drug be further pushed, to the extreme of complete salivation, with loosening and even falling out of the teeth. In the modern treatment of syphilis no such effects are desired, and are rarely attained. The milder of these manifestations readily disappear under appropriate therapy: tepid gargles of milk, flaxseed tea, or sweetened or demulcent water, containing one drachm (4.0) of potassium chlorate to the pint (500.0) of vehicle; a liquid and nutritious diet; abstinence from iced, alcoholic, spiced, acetous, and hot articles of food and drink; suspension of the mercurial; laxatives sufficient to secure complete evacuation of the bowels; and often the ferruginous and other tonics, preferably in solution.

Iodine and its compounds are useful in combination with mercury and without such union. They are more available for gummatous symptoms, but may be often employed with the greatest advantage in the milder symptoms of the disease. The articles of the class most used are iodine, iodipin, iodoform, and the iodides of lithium, sodium, starch, and potassium. No one of these is equal in value to the iodide of potassium; none enjoys to the same degree the confidence of the profession. It may be given alone or with mercury by the mouth; or it may be given by the mouth when mercury is employed by inunction or fumigation; or it may be given in alternation with one or more of the courses named.

It is always best administered in solution, gr. iij. to xx. (0.20 to 1.33), given in distilled water, milk, or any other vehicle preferred, such as cinnamon water, or one of the various syrups employed as vehicles. The method of administering the iodide of potassium in largest dose, gradually reached, from one drachm to an ounce (4.0 to 32.0) in the twenty-four hours, has been fully described in the paragraphs devoted to nervous syphilis. Employed with all due precautions, and administered with large draughts of pure water, it furnishes one of the most brilliantly effective of the measures at hand in the grave emergencies of the disease. When its morbid effects are produced, these may become apparent after the exhibition of the smaller doses. Among them may be named severe coryza, with œdema of the lids, lips, and glottis; salivation; gastrointestinal distress and tenderness; and a series of cutaneous eruptions. In the order of frequency the latter are acneiform papulo-pustules, furuncular lesions, purpura, tubercles, erythematous macules, bullæ, and eczemaform patches.

An enormous number of medicinal articles, beside those named, have been used in the treatment of syphilis. Some are indispensable in the management of most cases; some have a doubtful effect; many are absolutely worthless. In the first class may be named the ferruginous tonics; the mineral acids (only given simultaneously with the mercuric bichloride); cod-liver oil; quinine and the vegetable bitters; alcohol, judiciously administered; and, in particular, the fluid extract of erythroxylon coca, first warmly recommended by Taylor in the management of syphilis, and fully indorsed by the writer, who has employed it with advantage in many cases. In the second class may be named sarsaparilla (probably having no other than a purely "stomachic" value); the "McDade formula" (equal parts of the fluid extracts of smilax, sarsaparilla, stillingia sylvatica, kappa minor, and phytolacca decandra, with one-half of one part of the tincture of xanthoxylum carolinianum), and Zittman's decoction (probably efficient chiefly for the mercury it contains). In the last class may be named nitric acid, gold, thuya, cascara, berberis aquifolium, and the mass of proprietary preparations, many of which, though advertised as "purely vegetable" compounds, depend for a short-lived popularity upon the mercury or iodine which they contain. None of the mineral springs, in this country or abroad, which enjoy a reputation in the treatment of syphilis supplies a water which can be demonstrated to possess a therapeutic value outside of the climatic, hygienic, and, indeed, medicinal effects obtained by residence and treatment by physicians in the districts where such springs are found. The waters of the well-known Hot Springs of Arkansas, in this country, have never yet been shown to possess any medicinal virtue; and the number of syphilitic patients who annually resort thither and reap some advantage from such a course are, for the most part, those who have been treated there by physicians with mercury or the iodine compounds. The so-called process of "syphilization" has not survived its brief period of notoriety. It was based upon a confusion respecting the nature of the syphilitic and the non-syphilitic sore, and is now a curiosity in the literature of medicine.

No limit can be set to the length of time which should be assigned for the treatment of the disease. The average patient requires careful observation and treatment for from two to four years. Many require this for a far longer period. Mild cases may require less. No guarantee of future immunity can be given any patient on the conclusion of treatment, though probably seventy-five per cent. of all the infected have no symptoms of returning disease after proper treatment by a competent physician. Two years of immunity from all symptoms should elapse after the conclusion of treatment, before a patient of either sex should be permitted marriage with a non-infected person, though in the case of women who have not reached the menopause and are regularly menstruating, this period may be somewhat shortened. Two years of immunity is required by some of the larger insurance companies before accepting life-risks of the infected. Syphilis, however, is, as a matter of fact, one of the most readily managed and promising of all diseases that affect the human race. As distinguished from them all, its prognosis in general may be pronounced good. It may often disfigure, but it rarely destroys, its victims. As against the frequent fatality in pneumonia, variola, typhoid fever, or erysipelas, its statistics include an overwhelming preponderance of infected subjects in whose later years it figures only among those indelible reminiscences which teach the sternest lessons of life.

James Nevins Hyde.

BIBLIOGRAPHY.

The literature of syphilis has accumulated to such an enormous extent that a full bibliography, in the limits assigned to this article, would be impossible. Appended is a brief but selected list of titles, embracing a few of the older classics of syphilitic literature and some of the modern standard treatises devoted to the subject:

TALLEY'S SPRINGS.—Mecklenburg County, Virginia.

POST-OFFICE,—Palmer's Springs.

Talley's Springs are located seventy-five miles southeast of Petersburg, and within eight miles of the Atlantic and Danville Railroad on the north, and eleven miles of the Seaboard Air-line on the south. The situation is in a beautiful valley, the surface being clothed in a magnificent growth of original oak. The country is moderately hilly in character, and the climate very genial and salubrious. The springs have never been developed, but the waters have been resorted to by residents of the district for many years, and numerous cases are cited which illustrate their beneficial effects. A partial analysis has shown the presence of lithia, sulphur, and iron. A strong odor of sulphuretted hydrogen pervades the neighborhood. The water is said to have a wonderful preservative power. We are informed by Mr. G. W. Davis, the owner, that a small green log which has lain in the spring between thirty and forty years is still perfectly sound. It is stated that the advantages of these strong waters and the many attractive features of the neighborhood will soon be turned to good effect and a desirable summer resort established. Palmer's Springs, which also possess a local reputation, are two miles away.

James K. Crook.

TAMARIND.—(*Tamarindus*, U. S., P., B. P.; *Pulpa Tamarindorum Cruda*, P. G.; *Tamarinier*, Cod. Med.) The preserved pulp of the fruit of *Tamarindus Indica* (fam. *Leguminosæ*). The tamarind is a large, handsome, widely spreading, locust-like tree, with rough, dark-gray

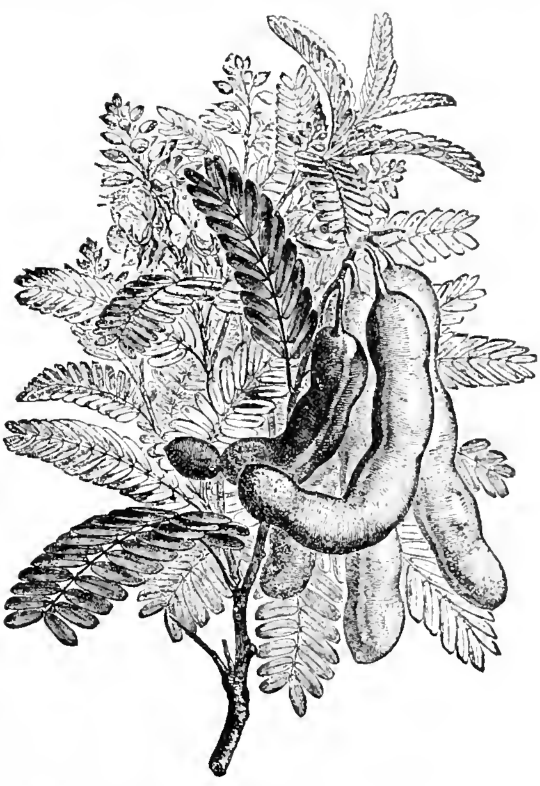

FIG. 4593.—Tamarindus Indica. Flowering branch with fruit. (Baillon.)

bark, and rather small, cassia-like, abruptly pinnate leaves. The fruit is a flattened, curved, solid "pod," from three to six or more inches long; smooth, yellowish-brown externally, with a brittle shell, and a firm acid pulp surrounding the seeds. The pulp contains a skeleton of fibrous bundles running lengthwise over the seeds. The tamarind tree grows now in all tropical countries, and is, besides, extensively cultivated. It came originally from the Old World, presumably from Africa, but is equally abundant in India, Australia, and the West Indies. When the fruits are ripe, the outer shell becomes brittle and is broken between the fingers and removed, the entire contents being then packed in kegs and covered with boiling syrup. In this way the West Indian tamarinds, which comprise most of those that reach our market, are prepared. In the East, sugar is often used instead of syrup, or they may be packed dry, without any sweetening, in a hard, semisolid mass.

Preserved tamarinds, as they reach us, are in a moist, reddish brown, pulpy, stringy mass, with numerous flattish-quadrangular, smooth seeds, and a little thick, dark syrup. They have a pleasantly sweet and acid taste. Mixed with water, they make a pleasant acid drink, which was formerly used in fevers and other forms of sickness. They are much less employed at present.

Composition.—Citric acid, eight or nine per cent., is the important constituent. About one and one-half per cent. of tartaric acid, a little malic acid, and, say, three per cent. of potassium bitartrate, are adjuvants to the former, and add to the acidity of the fruit. Gum, jelly, and ordinary vegetable matters, and, in our preserved tamarinds, the sugar that is added, complete the list of constituents.

Uses.—Tamarinds are rather an agreeable luxury than a medicine and in some countries are consumed extensively as a preserve. They possess some slight laxative properties, like prunes, barberries, figs, and other acid and sugary fruits. Here they are used to make a refreshing acid drink or as an adjuvant to some laxative compound. The Confection of Senna (*Confectio Sennæ*, U. S.) contains ten per cent. of them. The dose of tamarinds is indefinite.

W. P. Bolles.

TAMPA, FLORIDA.—This winter health resort, which acquired a somewhat unpleasant notoriety during the Spanish-American War on account of the hardships and illness suffered by the United States troops en route to Cuba, is situated about midway of the peninsula of Florida, on the Gulf side, at the head of Tampa Bay. It is about twenty-five miles distant from the coast, in Lat. 27° 57′ N., and has a permanent population of 15,839. It is one of the important commercial cities of Florida, and has extensive manufacturing interests, principally in cigars, employing large numbers of Cubans. There are various churches, an opera-house, street cars, electric lighting and water works, sewers, and clean-paved streets. Port Tampa, where the largest steamers land, is nine miles from the city, with which it is connected by rail, and from here steamers leave for Havana and various Gulf ports.

On the opposite bank of the Hillsborough River, at the mouth of which Tampa is located, is the Tampa Bay Hotel, situated in a beautiful park of one hundred and fifty acres, with a botanical garden containing a great variety of native and imported trees and plants. This hotel is one of the most imposing and extensive in Florida—the land of extravagant buildings of this sort. It is of Moorish architecture and contains nearly five hundred rooms, and is most luxuriously equipped. Connected with it is a casino, with a swimming pool, and an exposition building. There are several other hotels in the city proper, and one at Port Tampa. There are many opportunities for fishing, hunting, boating, and driving, and a variety of excursions about the beautiful bay. The surrounding country is sandy, but nevertheless supports a luxuriant tropical vegetation, groves of orange, lemon, and pine trees abounding.

The climate is a warm, equable, moist one, the mean annual temperature being nearly that of Cairo, Egypt. Both in climate and vegetation Tampa partakes of the characteristics of southern tropical Florida. It is well to remember that it was in May, June, and July that the United States troops congregated at Tampa, not the season when the visitor or invalid resorts to a warm country. Moreover, it was probably quite as much due to the sudden assemblage of a large body of men at this point as to the climate that the illness occurred. On account of the humidity and enervating quality of the climate, such a resort as Tampa is not favorable for tuberculosis; but it is useful for a variety of cases needing a mild, equable, sunny, winter climate, as has been indicated in the article upon *Florida* in Vol. IV. of the Handbook.

The accompanying chart gives the various climatic data for the four winter months and also for July. The characteristic features are seen to be mildness and equability of temperature, a high humidity, much sunshine, and a comparatively high annual rainfall, the larger part fall-

ing during the summer, features common to all the coast resorts of the Florida peninsula.

Tampa is readily reached by rail direct, or one can make a portion of the journey by water.

Edward O. Otis.

TANNAL, aluminum basic tannate, $Al_2(OH)_4.(C_{14}H_9O_9)_2 + 10H_2O$, is a brownish-yellow powder formed by precipitating an aluminum salt with tannic acid in the presence of an alkali. It is employed as an astringent dusting powder for wounds and ulcers, and as an insufflation in catarrhal conditions of the nose and throat. It is insoluble in water, but its combination with tartaric acid dissolves readily and is known as "soluble tannal." The solution, however, slowly decomposes.

W. A. Bastedo.

TANNALBIN is a tasteless, odorless, light-brown powder made by drying tannin albuminate at 110°–120° C. It is light and bulky and contains about fifty per cent. of tannic acid. It is insoluble in water or the gastric juice, but slowly dissolves in alkaline media, as in the intestine. Though tannalbin has very little astringency, the weight of evidence indicates that it is as efficient in diarrhœal conditions as any of the astringent drugs. It presumably sets free its tannic acid in the intestine, since Leonard Weber, Einhorn, Vierordt, and many others report an apparently prompt astringent action in tuberculous enteritis, enterocolitis, the summer diarrhœas of children, and acute or chronic dysentery. Most authors claim that it does not act at all in the stomach, but W. H. Porter recommends it in chronic catarrhal conditions of that organ, stating that its free administration arrests the excessive secretion of mucus. It is administered in capsule or in mixture, or in combination with small doses of calomel, or mixed with starch water as an enema. The dose for an adult is about 1 gm. (gr. xv.) several times a day. Ten grams (ʒ iiss.) a day have been given for several days without untoward effect.

W. A. Bastedo.

TANNIC ACID.—(*Acidum Tannicum*, U. S., Br., Ger. *Gallotannic Acid. Digallic Acid. Tannin.* $HC_{14}H_9C_9 = 321.22$.) An organic acid obtained from nutgall. A light-yellowish amorphous powder, usually cohering in the form of glistening scales or spongy masses, odorless, or having a faint, characteristic odor and a strongly astringent taste; gradually turning darker when exposed to air and light.

Tannic acid is freely soluble in both alcohol and water, as well as in glycerin. The characteristic blue-black color produced in a solution of tannic acid when a ferric salt is added forms the basis of tests for its presence. The form of tannic acid here considered is characterized by its convertibility into gallic acid, of which it is the anhydride. Although generally stated that it occurs in some other varieties of gall and in several other vegetable substances, certain differences are perceptible in these, and it has been questioned whether any of them can be considered as identical with the one under consideration. It may be extracted from the powdered galls by several processes. The most convenient method is to exhaust the latter with warm water and then thoroughly remove the impurities by churning with ether. The most common impurity present is resin, though after a time more or less gallic acid is likely to be formed, if carelessly preserved, the properties thus becoming weakened. Tannic acid is associated in the plant with more or less glucose, a part of it apparently combined as a glucoside, and this glucose often exists as an impurity of tannic acid.

Incompatibility.—The wide distribution of tannic acid, or its associates in the group, among vegetable drugs, lends great importance to its numerous incompatibilities, the more important ones being here stated. Tannin is slowly destroyed by remaining in aqueous solution, the process hastened by heat. Alkaloidal salts in aqueous or weak alcoholic solution are decomposed by tannin, their tannates, which are but slightly soluble in water, being precipitated. Other organic substances whose solutions are precipitated by tannic acid are albumen, gelatin, gluten, starch hydrate, and many glucosides and amaroids. A solution of antipyrin is also precipitated and iodoform is decomposed. Tannin in a solution of iodine prevents the latter from turning starch blue. Tannic acid is incompatible with ferrous salts, giving a gelatinous precipitate, and with ferric salts, giving a black color to a weak solution (its physiological action being not thus destroyed), and a black precipitate with a strong one, the strength correspondingly weakened. Solutions of salts of lead, copper, silver, chromium, mercury, bismuth, antimony, and most other metals yield tannates as precipitates, and nitric acid converts it into oxalic acid. With sulphuric, nitric, and hydrochloric acid, precipitates are yielded. Hydriodic acid is formed when tannin is added to iodine with water. Oxidizing agents are reduced by tannin. The stronger of them, like potassium chlorate, may produce explosions when triturated with tannic acid. With spirit of nitrous ether or amyl nitrite, a gas is yielded. Chlorine, iodine, and bromine are incompatible. Lime-water and tannin yield a precipitate, as do potassium and ammonia and their carbonates.

The physiological actions and uses of tannic acid depend almost wholly upon its chemical property of coagulating albumen in the form of a tannate, and this is especially true of its local action. In this way, the following effects are produced: A protective film is formed upon raw surfaces; bleeding orifices, if small, are closed by blood clots in their mouths and by a contracting clot about them; relaxed muscular tissue is contracted, thus increasing the hæmostatic effect; it coagulates the saliva and buccal mucus, and it is probably due to its mechanical action that the taste and general sensation of the mouth are diminished; in the same way it blunts the appetite and checks digestive activity, but arrests gastric and intestinal hemorrhage, as well as intestinal discharges, the latter effect not to be confounded with that of a stimulation of the vaso-motor nerves by volatile oils and other stimulants. Here again the mechanical blunting of the nerve endings results in a decrease of the peristaltic action, tannic acid being thus one of our most important constipating agencies. Here its local action may be said to end, while its systemic action becomes that of gallic acid, to which the reader is referred. It may be mentioned, however, that tannic acid has a distinct irritating tendency, which becomes apparent when overdoses are taken. In this way it may act as an emetic or even as a purgative.

The uses of tannic acid thus fall naturally into two classes, one of which is to be found discussed under gallic acid. Its chief local uses are to protect and stimulate the healing processes in all simple ulcers and in skin diseases which exhibit a superficial inflammatory tendency. Mild hemorrhages of the skin or of the nares, mouth, stomach, or intestines may be promptly arrested by it, the dry powder being best where direct application is possible. Excessive and malodorous local perspirations are checked, as well as foul exudations from the mucous membranes of nose, throat, and uterus. At the same time, an overrelaxed condition of these membranes, as well as of the rectum when hemorrhoids are present, is promptly corrected, although the effect is likely to be but temporary. Acute inflammatory conditions of the fauces, and to a less extent of the stomach, are often promptly relieved. Inhalation of a spray of tannic acid solution will check many cases of hæmoptysis, and this method, when possible, is much more efficient than its internal administration. The ordinary dose is gm. 0.06 to 0.3 (gr. i.–v.), but this is often largely increased in order to check hemorrhage. The official preparations are the styptic collodion, the glycerite, and the ointment, each of twenty-per-cent. strength, and the troches, each containing about one grain. A five-per-cent. or ten-per-cent. aqueous solution is often used for irrigating the nares or the vagina.

Henry H. Rusby.

TANNIGEN, di-acetyl tannin, $C_{14}H_8(CH_3CO)_2O_9$, is a yellowish-gray, odorless, and tasteless powder, prepared by the action of acetic anhydride or acetyl chloride on tannic acid dissolved in glacial acetic acid. It dissolves in dilute solution of sodium borate or phosphate and in alcohol, is slightly soluble in ether, and is insoluble in water, though it tends to absorb moisture from the air. It is decomposed by alkalies, and is colored blue-black by ferric salts. Passing unchanged through the stomach, it is broken up in the intestine, where the slow liberation of tannic acid gives a mild and continuous astringent effect. In diarrhœa, dysentery, and especially the summer diarrhœas of children, Clark, Biedert, Escherich, and Ewald have found it superior to the preparations of krameria, catechu, hæmatoxylon, and other vegetable astringents. Williams of Boston, Müller, and others recommend it in the diarrhœas of tuberculosis. The dose is 0.1 gm. (gr. iss.) several times a day for young children, and 0.35–0.7 gm. (gr. v.–x.) for adults.

Clark suggests the following for use in leucorrhœa: ℞ Tannigen 4 gm. (ʒ i.), boric acid 8 gm. (ʒ ij.), zinc sulphate 0.7 gm. (gr. x.) fluid extract hydrastis 8 c.c. (ʒ ij.). Dissolve in a cup of hot water and add to three quarts of hot water for injection. Tannigen has also been employed as an insufflation in nose and throat affections.

W. A. Bastedo.

TANNOFORM, methylene di-tannin, methylene di-gallic acid, $CH_2(C_{14}H_9O_9)_2$, is a condensation product obtained by adding a solution of formaldehyde to a solution of gallotannic acid in hot water and precipitating with hydrochloric acid. It is a loose pinkish-white powder, insoluble in water or acids and soluble in alcohol; it dissolves in alkalies with decomposition.

In the intestine tannoform sets free tannic acid and formaldehyde, and has been so used as an intestinal astringent and antiseptic. But it is not very widely employed thus, because of the possible irritation of the formaldehyde. It is a clean, dry antiseptic and deodorizing powder, and is used either pure or diluted with starch or talcum. In wounds, ulcers, and bedsores it seems to have marked healing properties, in hyperidrosis and bromidrosis it is siccative and deodorizing, and in moist eczema, pruritus, intertrigo, and burns it forms a serviceable dusting-powder. In chronic catarrh of the nasal passages, especially in ozæna, it is used as an insufflation.

Similar compounds prepared from formaldehyde and the tannins of aspidosperma, oak bark, and cinchona are called respectively *quebrachinoform, querciform,* and *quinoform.*

The bismuth salt of tannoform is "*bismal.*"

W. A. Bastedo.

TANNOPIN or Tannon, $(CH_2)_6N_4.3C_{14}H_{10}O_9$, is a condensation product of tannic acid and hexamethylenetetramine (urotropin). It contains eighty-seven per cent. of tannic acid and is a brown, odorless and tasteless, slightly hygroscopic powder, which is insoluble in water, alcohol, ether, or weak acids, but dissolves, probably undergoing change, in weak alkalies. It is said to liberate tannic acid and formaldehyde in the intestine, and for this reason is employed as an intestinal antiseptic and astringent. Schreiber, Meier, and Tittel have reported highly satisfactory results in tuberculous enteritis, and in acute, subacute, and chronic diarrhœas. The dose is 0.2–1 gm. (gr. iij.–xv.) several times a day.

W. A. Bastedo.

TANNOSAL, or Creosal, is the tannic acid ester of creosote, representing sixty per cent. of the latter. It is a dark-brown powder with biting taste and a slight odor of creosote, and is soluble in water, alcohol, and glycerin. As it sets free tannic acid and creosote in the intestine, it is employed as a means of administering creosote in pulmonary tuberculosis, or as an intestinal antiseptic and astringent. The dose is 0.2–1 gm. (gr. iij.–xv.) several times a day. As it is hygroscopic, a solution is marketed containing 1 gm. (gr. xv.) in each tablespoonful

W. A. Bastedo.

TANSY.—(*Tanacetum*, U. S.; *Tanasia*, Cod. Med.) The dried leaves and top of *Tanacetum vulgare* L. (fam. *Compositæ*). Tansy is a perennial herb, native of Europe and Southern Asia. It was introduced into the United States as a cultivated aromatic and has become abundantly naturalized as a weed along roadsides and in waste places. The stems are somewhat tufted, erect, nearly simple, a foot or two, rarely a yard, high; leaves shortly and stoutly petioled, rarely exceeding 20 cm. (8 in.) long and 10 cm. (4 in.) broad, obovate when flattened, pinnate, the pinnæ about ten or twelve pairs, linear-oblong, obtusish, pinnatifid, their segments oblong, acute, incisely serrate or lobed; thin, with a strong midrib, smooth, dark-green, finely depressed-glandular; flower heads in a small, loose, terminal corymb, long-peduncled, yellow, nearly 1 cm. (about ⅜ in.) broad, having an imbricated, saucer-shaped involucre, a convex, naked receptacle, and numerous yellow tubular florets, which are perfect, or the outer circle pistillate; highly and peculiarly aromatic, the taste pungent and very bitter.

It contains the peculiar bitter substance *tanacetin*, which is amorphous, very hygroscopic, and soluble in both alcohol and water. This imparts the most of the bitter taste, although the volatile oil is also bitter. The latter exists to the extent of about one-fourth of one per cent., has a specific gravity of about 0.955, and is of a yellowish-green color, becoming more or less brown upon exposure. It is soluble in about three parts of seventy-per-cent. alcohol. It is highly aromatic, bitter, and pungent, its important constituent being *thujone* (*tanacetone*). Tansy also contains some tannin, malic acid, and other unimportant constituents.

Besides the properties of tansy as one of the more powerful aromatic bitters, together with the diaphoretic and diuretic properties of its class, it and its oil have been used from time immemorial as anthelmintics. Oil of tansy, and tansy itself in large doses, are poisonous, the general symptoms being similar to those of the coniferous oils (juniper, turpentine, savin, etc.). These symptoms are: great irritation, vomiting, abdominal pain, painful diuresis, convulsions, coma, and death. They belong to the more painful class of poisons. They are also powerfully emmenagogue, though the symptoms are painful and the use of the drug for this purpose is not desirable. They are liable to cause abortion, though they usually fail of this purpose when taken with such intent, as is commonly done.

The dose of tansy is 1 to 4 gm., usually in the form of the fluid extract (1 to 4 c.c.), though this represents the extreme dose which should be used. The oil may be administered in doses of ♏ i.–v. So little as a fluid-drachm of the oil has proved fatal.

Henry H. Rusby.

TAPHOSOTE is a grayish syrupy liquid of faint odor and taste and containing tannic acid, creosote, and phosphoric acid. It is employed in pulmonary tuberculosis and as an intestinal antiseptic and astringent. The dose is 4 c.c. (ʒ i.).

W. A. Bastedo.

TAPIOCA.—*Manioca; Mandioca; Cassava Starch.* The starch of *Manihot utilissima* Pohl ("Sweet Cassava") and of *M. Aipa* ("Bitter Cassava"), (fam. *Euphorbiaceæ*).

The genus Manihot contains some eighty species of tropical America. Besides the above species, used as food, the genus is important as a rubber-yielder, by the species *M. Glaziovii* Muell. Arg., a small tree of Brazil. Our only interest in the Manihot is from a dietetic standpoint, if we except the poisonous properties of the bitter variety, due to the presence in it of hydrocyanic acid. The starch-yielding part is the cluster of large fleshy roots, which much resemble sweet potatoes, save in their paler color. These roots, under the above names, as well as that of *Yuca*, constitute the principal edible root crop of Brazil. Their use, boiled and baked, for the table, as well as for bread-making, far exceeds that for the manufacture of tapioca. Even among savage tribes, who had never before seen white men, the writer has seen it thus in use. Although slightly sweetish, it is far more like a white than a sweet potato in flavor. The finely ground pulp, pressed, dried, and then pulverized, is cassava meal, and is made into bread, in huge circular cakes, a yard in diameter and nearly a half-inch in thickness. These are transported in bales, bound with leaves. Their special advantage is to be found in their long-keeping qualities. The taste is negative rather than strongly pronounced, thus well qualifying the article for staple use. Bitter cassava is rarely used in its entirety, but is made into bread, or tapioca, after the poison has been dissipated by fermentation and other processes. The extraction of cassava starch as commercial tapioca differs only in details, as regards convenience, from that of other starches. It is, however, partly hydrated to cause it to form in the peculiarly irregular and hard masses known to us. In many parts of Brazil, dry tapioca is served at table, as a side-dish, as a substitute for bread. This is usually in smoothish, yellowish grains, resembling pebbles, very hard and trying to both teeth and gums. Tapioca is merely an amylaceous food, and has no medicinal properties.

Henry H. Rusby.

TAR.—*Pine Tar* (*Pix Liquida*, U. S. P., B. P., P. G.). An empyreumatic oleoresin obtained by the destructive distillation of the wood of *Pinus palustris* Miller, and of other species of *Pinus* (fam. *Pinaceæ* or *Coniferæ*).

The essential features of tar distillation are the partial burning of a wood rich in turpentine, the heat thus produced serving to expel from the wood near it the volatile and liquid products present, or which form during the process, the volatile ones ascending into the flame and being destroyed, the heavier ones settling downward and being collected as tar. It is almost altogether performed in rude stills constructed in the forest where the wood is gathered. The still is formed by stacking the wood upon a level and hardened spot of ground, surrounding it with a trench leading into a pit and surrounding the stack with a circle of earth and sods, thus preventing the free access of air. The stack is then ignited at the top and slowly burns downward, the expelled tar gradually trickling to the bottom and flowing into the pit, from which it is removed and stored in barrels, in which it hardens and is marketed. The wood used consists chiefly of dead branches and trunks and stumps of the trees which have been killed by tapping for turpentine. Tar is thus described by the Pharmacopœia:

"Thick, viscid, semi-fluid, blackish-brown, heavier than water, transparent in thin layers, becoming granular and opaque with age; odor empyreumatic, terebinthinate; taste sharp, empyreumatic.

"Tar is slightly soluble in water, soluble in alcohol, fixed or volatile oils, and solution of potassium or sodium hydrate.

"Water agitated with tar acquires a pale yellowish-brown color and an acid reaction, yields with ferric chloride T.S. a transient green color, and is colored brownish-red by an equal volume of calcium hydrate T.S."

The composition of tar is highly complex. Its constituents are, as might be expected, closely similar to those of coal tar, the sources of the two differing more in the length of time consumed in the production than in the essentials of the process. A large number of these constituents and their products are considered under separate titles in this work. The more important constituents are contained in the oil, considered below, and in the pyroligneous acid, which, when distilled off, leave *common pitch* or *naval pitch* (*Pix navalis*). In the distillate the acid and the oil separate, either on account of their different distilling points or on account of their different specific gravities. The acid is a source of acetic acid and numerous other substances. The relative percentages of the different portions, as also of the constituents of the latter, differ widely in different tars, depending upon the kind of wood employed, its condition and character, the details of the distillation, etc., so that both tar and tar oil are exceedingly irregular in character. The properties of tar are considered below, under Oil of Tar. Tar is itself employed externally, chiefly in the form of the *ointment* (*Unguentum picis liquidæ*, U. S. P., consisting of 50 parts of tar, 12½ parts of yellow wax, and 37½ parts of lard), and internally chiefly in the form of the *syrup* (*Syrupus picis liquidæ*, U. S. P., containing 7½ parts of tar, 10 of glycerin, and 80 of sugar, with water to make 100). The dose of tar is 1 to 4 gm. (grs. xv. to lx.); of the syrup, about four times as much. Tar is often given in the form of the water, made by thoroughly stirring four ounces of tar in a pint of water, allowing to settle, and decanting. Of this, half a tumblerful may be taken three or four times daily, and it is an excellent antiseptic diuretic.

Oil of tar (*Oleum picis liquidæ*, U. S. P.) is thus described in the Pharmacopœia: "An almost colorless liquid when freshly distilled, but soon acquiring a dark reddish-brown color, and having a strong, tarry odor and taste. Specific gravity about 0.970 at 15° C. (59° F.). It is readily soluble in alcohol, the solution being acid to litmus paper." It contains, as its principal part, creosote, which in turn consists of *guaiacol*, cresol, creosols, and phlorol, and which has been elsewhere considered; carbolic acid in small amount, toluene, xylene, paraffin, naphtalene, pyrocatechin, etc.

Oil of tar possesses, in lesser degree, the antiseptic and poisonous properties of the substances which it contains, as above stated. It has at the same time the diuretic and diaphoretic, as well as the irritant properties of the closely related substance oil of turpentine, though in milder degree, but is more distinctly expectorant than that substance. Its uses, both professional and domestic, depend directly upon these properties. As a counter-irritant, its action is very mild, and it is an excellent chest application for young children. Its antiseptic action is often secured as a constituent of mixtures destined for inhalation purposes. Internally, its chief use is in bronchitis, especially the chronic form, and its internal administration is commonly combined with its use as an application to the chest. Oil of tar is less frequently administered than the syrup, but may be given in doses of ♏ i. to v. or even ♏ x. There is no official preparation. *Henry H. Rusby.*

TARASP-SCHULS.—This health station and spa is situated in the Lower Engadine Valley, thirty four miles from Samaden, with which it connects by diligence twice daily. It consists of the three places, all near together, Tarasp-Schuls, Schuls, and Vulpura. Schuls, 3,970 feet above sea level, is the largest village in the Engadine, and contains about a thousand inhabitants. It is picturesquely situated on a slope of the valley, with the Inn below and, opposite, a stately range of well-wooded mountains, and is divided into an upper and a lower town, in the former of which most of the hotels and pensions are situated. On the high-road separating the two portions of the town is situated the bathing establishment, with eighteen bath- and two douche-rooms for iron and fresh-water baths.

Vulpura is a suburb consisting of large and well appointed hotels, lying on the opposite side of the river from Schuls, and about two hundred feet above it, on a thickly wooded height. It is at a distance of twenty minutes from the Kurhaus Tarasp, by a good road.

On the high road about a mile to the west of Schuls are the baths of Tarasp, consisting of an extensive Kurhaus with a "pump-room" and baths, and surrounded with pleasant gardens and parks. The whole country about is most attractive, and affords innumerable opportunities for walks and excursions in every direction, amidst grand scenery and in a pure mountain atmosphere. One who desires to take a course of these waters can conveniently reside at any of the three localities.

The climate of this region is somewhat milder than that of the Upper Engadine, although it partakes of the same general characteristics, viz., a rarefied atmosphere, moderate temperature, dry air and free from dust, protection from high winds, and increased intensity of the sunlight and heat. The mean temperature during the season (June 1st to September 15th) is 57.14° F.; the maximum, 87.08° F.; and the minimum, 33.8° F. The mean relative humidity is from 65 to 75 per cent., and there is an average rainfall of 9.40 inches. There are on an average during the season 39 perfectly clear days, 27 fair ones, 34 more or less overcast, only 6 or 8 of which are actually rainy.

The effect of the climate iss timulating and tonic, and may be rather severe for delicate persons, as sudden changes occur. For one, however, fairly robust and who desires to unite the high mountain air cure with a course of the waters and baths offered here, hardly a more admirable and charming resort could be found. "Scarcely another station in Europe," says Linn, "unites so many important qualities."

There are eight cold mineral springs that are used at this resort, although there are many more in the neighborhood. Four of the springs used yield sulphated alkaline waters of the class known as the "Cold Glauber's Salt Springs," similar to those at Carlsbad. The Lucius and Emerita Springs of this class are used for drinking and bathing; and the Ursus- and Neue Bade Quelle are only used for bathing. The rest of the springs are iron, yielding a gaseous chalybeate water known as "Sauerwasser." Of these the Bonifacius is used for drinking alone; the Wy for drinking and bathing; while the Carola is used for bathing alone. The four springs of Sotsass are used as a favorite table water. Compared with the waters of Carlsbad, Marienbad, Kissingen and Vichy, the Lucius Spring at Tarasp contains about the same amount of sulphate of soda as Carlsbad, but nearly or quite three times as much carbonate of soda and chloride of sodium, and at least three times as much carbonic acid. The carbonate of soda is slightly in excess of that found in the water of Vichy, and the chloride of sodium is about a fourth less than at Kissingen. Marienbad contains more sulphate of soda, but less of the other ingredients.

The analysis of the Luciusquelle by Husemann is as follows:

In Sixteen Ounces of the Water there were:

Sulphate of soda	16.131	grains.
Sulphate of potash	2.916	"
Borate of soda	1.312	"
Nitrate of soda	.006	"
Chloride of sodium	28.216	"
Chloride of lithium	.022	"
Bromide of sodium	.173	"
Iodide of sodium	.007	"
Bicarbonate of soda	35.425	"
Bicarbonate of ammonium	.507	"
Bicarbonate of lime	18.800	"
Bicarbonate of strontium	.005	"
Bicarbonate of magnesia	7.521	"
Bicarbonate of ferric oxide	.165	"
Total amount of fixed solids	113.216	"
True free carbonic acid	33.92	cu. in.

Of the Chalybeate Springs the Bonifacius is the strongest, containing 0.015 per thousand parts of the bicarbonate of iron. The iron baths are heated by a tube through which steam passes, so as to cause comparatively little of the carbonic acid to escape.

Three hours distant from Schuls are the acidulous mineral springs of Val Sinestra, containing a little arsenic. These waters are brought daily to Schuls.

As to the therapeutics of these waters, the four soda acidulous springs are more or less successfully employed in many different functional and organic diseases and conditions, such as obesity, chronic constipation, hemorrhoids, dyspeptic conditions, gall-stones, glycosuria of fat persons, affections of the kidneys and bladder, diabetes, gout. By warming the water before drinking, it can be made to resemble more closely Carlsbad water.

The Chalybeate Springs are used in anæmia and debilitated conditions. In combination with the hydrotherapeutic processes massage is given, and the diet is carefully regulated. Good physicians who speak English are found at this spa.

Most visitors taking the waters usually frequent the pump room at the Kurhaus Tarasp at an early hour in the morning, at which time there is music. There is a very delightful path along the river from Schuls to Tarasp, a walk over this occupying about half an hour; and the hotel-keepers at Schuls provide (gratis) conveyances which run at frequent intervals during the day between these two places. It is well to be provided with warm clothing, for the weather is frequently cool.

There are several ways of reaching Schuls: by rail to Davos Platz (soon to be extended to and beyond Schuls), and thence by diligence over the Fluela Pass; or, by rail to Landeck, and thence by diligence in eight hours. Coming from the south, one can go by rail to Chiavenna, and thence by diligence over the Maloja Pass and through the Upper Engadine, a long ride, but through grand and delightful scenery; by this route it is well to break the journey at Samaden. *Edward O. Otis.*

FIG. 4591.—View of Tarasp-Schuls in the Lower Engadine, Switzerland.

TARAXACUM. See *Dandelion.*

TARTARIC ACID ($H_2C_4H_4O_6$).—"An organic acid usually obtained from argols. Colorless, translucent, monoclinic prisms, or crystalline crusts, or a white powder, odorless, having a purely acid taste and permanent in the air." (U. S. P.).

Tartaric acid is soluble in both alcohol and water, very freely in the latter. It forms during the process of fermentation of wine, in the form of the bitartrate or acid tartrate, which is scraped from the insides of the casks in a mass called argols or tartar, or, after purification, cream of tartar. This is converted into calcium tartrate by the action of calcium carbonate in the form of powdered chalk. The calcium is then removed by sulphuric acid, setting free the tartaric acid, which must be carefully freed from traces of potassium, calcium, and sulphuric acid.

Tartaric acid has no special medicinal properties as distinguished from those of its class. It is one of the mild acids recommended for use in alkali poisoning, and it is useful (in the form of the effervescent powder or

Seidlitz powder) for freeing carbonic acid in the production of carbonated liquors. It is also much used as a fraudulent substitute for citric acid in the production of citrate-of-potassium solution. *Henry H. Rusby.*

TARTARIC ACID DIPHENYL ESTER ($C_6H_5COO.-CHOH_2$) is a condensation product of phenol and tartaric acid recommended in doses of 0.35 gm. (gr. v.) in gout and rheumatism. It occurs in fine silky needles of faint aromatic odor, which are insoluble in water or cold alcohol, but dissolve in hot alcohol, ether, or glycerin.
W. A. Bastedo.

TARTARLITHINE is a granular effervescent preparation of lithium bitartrate, a salt analogous to cream of tartar. As a uric acid solvent 0.35–0.7 gm. (gr. v. to x.) are given three or four times a day dissolved in a tumbler of water. *W. A. Bastedo.*

TARTROPHEN is a compound of phenetidin and tartaric acid analogous to *citrophen* (phenetidin and citric acid). Its uses and dosage are the same as those of citrophen, but clinical data are lacking.
W. A. Bastedo.

TASTE.—1. Definition and Introduction.—Taste is a special sense. A special sense is one provided with specialized end organs and located in structures that are especially adapted to serve the organism in receiving and conducting the stimuli to the sensory end organs.

The sense of taste possesses as specialized end organs the gustatory or taste buds, located on the surface of the tongue, the fauces, the soft palate, and the epiglottis. That the taste buds are the sole organs of taste is far less certain than it is that the eye is the sole end organ of vision. It is true that those portions of the oral mucous membrane which possess the sense of taste are the only places where the taste buds are found. On the other hand, there are many other nerve fibres which possess filaments and other endings in this same region. The other nerve endings in this region are similar to those found in other parts of the body, and serve in those parts the tactile and temperature senses. The tongue possesses the tactile and temperature senses to a high degree. Although our conclusion that the gustatory buds are the sole end organs of taste is reached by a course of inductive reasoning, we may feel secure that our conclusion is a tenable one.

2. Anatomical Considerations.—The taste bud is an epithelial structure composed of spindle-shaped cells grouped in a spheroidal mass with one pole at the surface of the epithelium. The cells may be classified in two orders, the sustentacular and neuro-epithelial. The sustentacular cells when located on the surface of this spheroid are called tegmental cells, and are somewhat larger than those which make up the internal part of the bud. Lying between the sustentacular cells in the midst of the bud are the delicate, spindle-shaped, neuro-epithelial cells, whose nuclei are in the basal portion farthest removed from the epithelial surface and whose external ends terminate in delicate hair-like filaments. Surrounding the nuclear end of the neuro-epithelial cells is a copious arborization of the delicate terminal fibrils of the telodendria of the gustatory neurones. These arborizations may also be found in some cases to surround the inner ends of the sustentacular cells. The taste bud possesses at the epithelial surface a minute pore, through which substances in solution may pass into the taste bud and will be drawn by capillary attraction into the innermost spaces between the sustentacular cells and neuro-epithelium, and thus be brought into immediate contact with the gustatory nerve endings.

Those gustatory nerve fibres which leave the posterior third of the tongue, the fossæ, palate, and epiglottis, pass to the gustatory centre by way of the glosso-pharyngeal nerve. Those which leave the anterior two-thirds of the tongue pass at first into the lingual branch of the inferior maxillary division of the fifth nerve. They all leave the lingual branch and pass by way of the chorda tympani back to the seventh nerve. From here to the gustatory centre their course has not been definitely traced. The clinical evidence seems to favor the view that they pass by way of the seventh nerve into the base of the brain, while experimental evidence as well as observations on the embryonic development of the cranial nerves indicates that the fibres leave the seventh nerve at the geniculate ganglion and pass by way of the Vidian nerve and Meckel's ganglion back to the fifth. Leaving the final course of the lingual gustatory nerves to be determined by further experiment, we may rest assured that eventually they make their way to the same gustatory centre to which the glosso-pharyngeal fibres make their way.

3. Physiology of the Sense of Taste.—Many of the perceptions attributed to taste really depend quite as much upon smell as upon taste. We usually apply the term *flavor* to those sensations which depend upon both smell and taste; *e.g.*, one speaks of the flavor of roast beef or of coffee. The fact that closure of the nose impairs the flavor of the beef or coffee indicates that a part of the flavor is to be attributed to the sense of smell. The sense of taste alone seems to be confined to sensations arising from four distinct stimuli: (1) *sweet*, (2) *bitter*, (3) *acid*, (4) *salt*. All purely taste sensations are either modifications of or combinations of these four fundamental sensations. The sense of taste is excited usually by those substances which pass into solution—*i.e.*, insoluble substances are tasteless. It may be noted in passing that mechanical stimuli applied to the gustatory surface are capable of arousing sensations of taste, and the same is true of electrical stimuli. In the case of the latter, the fact that the cathode usually tastes bitter-alkaline, while the anode usually tastes acid, would seem to show that the efficient stimuli are the basic ions which gather at the cathode and the acid ions which gather at the anode respectively. Though this is undoubtedly the way to account for the taste of the cathode and anode in the constant current, it does not throw light upon the fact that taste sensations are also aroused by induction shocks.

The sensation will vary in strength with: (1) the size of the area stimulated, the sensation being more intense the greater the area stimulated; (2) the concentration of the solution, being more intense the stronger the solution; (3) the temperature of the solution, being more intense the nearer the temperature is to that of the blood; (4) the mechanical friction of the tongue against the palate, being stronger with moderate friction than without it.

The sense of taste varies in acuteness (1) through certain hereditary influences, and (2) through cultivation. A good example of marked acuteness of taste acquired by cultivation may be found in professional tea-tasters and wine-tasters.

1. *To Determine the Acuteness of Taste.*—Make four standard solutions, as follows: (1) *Sugar*, 1 gm. of dry saccharose in 100 c.c. of distilled water. (2) *Quinine sulphate*, 1 cgm. in 1,000 c.c. of distilled water. (3) *Acetic acid*, 1 gm. of glacial acetic acid in 1,000 c.c. of distilled water. (4) *Salt*, 1 gm. of dry sodium chloride in 100 c.c. of distilled water.

In the use of these solutions prepare the gustatory surfaces by thoroughly rinsing the mouth with distilled water or with boiled water. Take a uniform quantity of the solution into the mouth at each observation. A convenient quantity is 4 c.c. or a common teaspoonful. Rinse the mouth before each new observation.

The following table gives results obtained by a number of observers. (The numbers indicate the number of parts of water to one of the substance to be tasted.)

Mr.	Sugar.	Quinine.	Acetic acid.	Salt.
A	700	1,000,000	7,000	425
B	600	500,000	8,000	500
C	....	250,000	1,400	....
D	300	400,000	3,000	700
E	700	......	4,000	400
F	400	400,000	6,000	600

Mr.	Sugar.	Quinine.	Acetic acid.	Salt.
G..............	333	400,000	6,000	....
H..............	500	400,000	4,500	480
I..............	500	450,000	6,000	325
J..............	650	200,000	7,500	325
Average.......	1 to 520	1 to 444,000	1 to 5640	1 to 469

Besides the results here recorded, numerous data were furnished by other observers.

This table and the supplementary data justify the following conclusions:

1. The acuteness of taste for sugar varies from 1 part of pure cane sugar in 300 parts of water to 1 in 708, with an average of 1 in 520.

2. The acuteness of taste for salt varies from 1 in 325 to 1 in 700, with an average of 1 in 469.

3. The acuteness of taste for acetic acid varies from 1 in 3,000 to 1 in 8,000, or an average of 1 in 5,640.

4. The acuteness of taste for sulphate of quinine varies from 1 in 200,000 to 1 in 1,000,000, with an average of 1 in 444,000.

From these results it is evident:

5. That there is considerable individual variation.

6. That the taste is most acute for the less common stimuli of bitter and acid than for the more common stimuli of salt and sweet.

7. Several subjects recorded a marked decrease in the acuteness after the use of tobacco.

8. One subject recorded a noticeable increase in the stimulation when the solutions were warmed from 20° to 40° C.

9. One observer found that the tip and edge of the tongue were more acute than other parts of the tongue in detecting slight differences in the strength of the solutions.

10. One observer, reporting a series of very careful experiments upon four individuals, three of whom are members of the same family and accustomed to the free use of salt and vinegar in their regular diet, concluded that the fourth individual, not accustomed to the free use of salt and vinegar, has a greater sensitiveness for saline and sour substances than have the three individuals who are so accustomed.

As to the interval of time between the application of the stimuli and the taste perception, the observations seem to justify the following conclusions:

11. The interval between stimulation and sensation (latent interval) varies inversely as the number of papillæ per unit area in the portion of the gustatory apparatus stimulated.

12. The interval between stimulation and sensation varies directly as the blood supply of the part at the time of stimulation.

II. *To Determine Localization of the Sense of Taste, i.e.,* to find whether there are areas of gustatory region which are especially sensitive to particular stimuli—quinine, for example.

Solution.—Through the aid of a probang or a camel's-hair brush apply to different limited areas of the tongue, palate, or fauces either the standard solutions given above or somewhat stronger solutions of the same substances.

Results.—The accompanying figure gives the results which coincide substantially with those of other observers: Outline of tongue showing location of tonsils (*T*), foramen cæcum (*F.C.*), circumvallate papillæ (*C.P.*), and fungiform papillæ (*F.P.*) upon the left side, while the right side shows the outline of the area particularly sensitive to quinine (——), acid (....), salt (—.—.—), and sugar (- - - -) respectively.

"O. Ehrwall has examined the different fungiform papillæ over the tongue with reference to their sensitiveness to taste stimuli. One hundred and twenty-five separate papillæ were tested with succinic acid, quinine, and sugar. Twenty-seven of the papillæ gave no response at all, indicating that they were devoid of taste fibres." [It may be suggested in passing that perhaps the twenty-seven papillæ were sensitive to salt alone.—W. S. H.]

"Of the remaining ninety-eight, twelve perceived acid alone, three perceived sugar alone, while none was found which reacted to quinine alone. The fact that

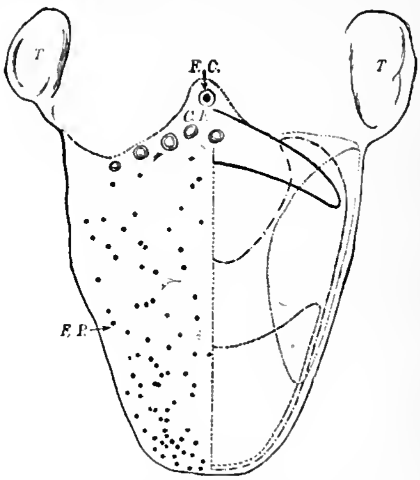

FIG. 4595.—Localization of Taste. Bitter, ——; acid, ...; salt, —.—.—; sweet, - - - -; *T*, Tonsils; *F.C.*, Foramen cæcum; *C.F.*, Circumvallate papillæ; *F.P.*, Fungiform papillæ. (Hall: "Text-book of Physiology." Lea Bros., Philadelphia.)

some papillæ respond to only one form of taste sensation is evidence in favor of the view that there are separate nerve fibres and endings for each fundamental sensation, but a majority of the papillæ (eighty-three) are provided with more than one variety of taste fibres." (Henry Sewall, in "American Text-book of Physiology.")

Winfield Scott Hall.

TATE SPRING.—Grainger County, Tennessee.

POST-OFFICE.—Tate Spring. Hotel and cottages.

ACCESS.—Viâ Morristown and Cumberland Gap Railroad to Morristown; thence ten miles by carriage to spring.

This resort is 1,400 feet above the sea-level, and is located in a charming valley environed by mountains 3,000 feet in height. It may be regarded as one of the strictly first-class summering places of the Tennessee Mountains. The beautiful and picturesque scenery and genial climate are supplemented by the addition of two excellent modern hotels and numerous cottages. There is but one spring, which yields one hundred and twenty gallons per hour. The following analysis was made in 1872 by T. S. Antisill, professor of chemistry in the National Medical College and chemist to the United States Department of Agriculture: One United States gallon contains (solids): Calcium sulphate, gr. 160.66; magnesium sulphate, gr. 32.91; sodium sulphate, gr. 8.50; potassium sulphate, gr. 1.54; sodium chloride, gr. 40.27; iron chloride, gr. 2.99; magnesium chloride, gr. 0.62; sodium iodide, a trace; calcium phosphate, gr. 1.14; calcium carbonate, gr. 21.56; silica, gr. 2.70; nitric acid, gr. 0.02. Total, 272.91 grains. The analysis shows a saline purgative water with tonic and alterative properties. It has been found beneficial in functional disorders of the nervous system induced by overwork and mental worry, in cases of hypochondria and insomnia, and in chronic metallic poisoning. Some forms of dyspepsia and liver disorders are also improved by its use. The water is now used commercially and shipped by the bottle, case, or barrel to any desired point.

James K. Crook.

TATTOO MARKS.—Tattooing consists in the introduction into the skin of insoluble colored substances which become encapsulated and thus form permanent stains. Microscopical examination of sections from tattoo marks shows that they consist of relatively large particles of pigment, situated part of them in the corium, but the larger part in the subcutaneous connective tissue. Particles of pigment are found also in the contiguous lymphatic ganglia. Powder stains, coal-dust stains, and similar stains produced by the accidental embedding in the skin of particles of colored substances, usually carbon, are in all essential characteristics identical with tattoo marks. One form of accidental marking of the skin to which attention should be called is the whitish marks which occasionally result from the precipitation of lead in the tissues during the use of subacetate-of-lead solution or lead and opium wash upon superficial wounds involving the connective tissue. The danger of these stains on the cornea from the use of subacetate of lead in the eye is well known. A staining of the skin which is in all essentials of the same character as these we are considering, but which is produced from within, is argyria, in which there is a precipitation of silver in the derma and subcutaneous tissue after the long-continued internal use of silver. The writer has seen a marked argyria in one case in which the silver was not being taken internally, but had been used daily during more than a year in the form of a solution of the nitrate for painting patches of leukoplakia buccalis.

Tattooing is one of the most primitive efforts of man at personal adornment. Like many other things that have their origin in vanity, various kinds of significance are attached to the practice, but the underlying reason for tattooing, not only among the primitive races, but among the civilized, rests probably upon an inherent barbaric taste for distinctive personal decoration. Among uncivilized peoples and among nations in a relatively low state of civilization, like the Orientals, the practice is general, and is often carried to the most extravagant extent. Among Caucasians, aside from its general use among sailors, it is largely confined to those individuals of both the lower and the higher classes who readily accept anything that is bizarre or that gives them a fancied distinction.

Brault divides tattooing among primitive peoples according to its significance, as follows: First, religious tattooing, as in the priests among the Polynesians; second, ornamental tattooing, seen in the Algerians, Tunisians, and in the inhabitants of Oceanica and Japan; third, therapeutic tattooing, practised in Tunis, in Egypt, and in the Congo region; fourth, distinctive tattooing, practised among the Arabs and negroes of Africa, for the purpose of defining not only different tribes, but also certain callings; fifth, obscene tattooing, which is found only rarely among savages, but which is very common among sailors and criminals.

Practical uses of tattooing are very limited. As a means of identification tattoo marks are of course valuable, and the tattooing of habitual criminals has been suggested as a means of their ready identification. Several years ago de Wecker suggested the tattooing in black of leucomatous areas on the cornea. The method has not had very wide application, and is of course not free from danger. Very recently the highly artificial suggestion has been made of tattooing the flush area of the cheeks to represent a healthy blush. It is interesting to try to imagine how this healthy blush would appear on the faded skin of later life.

Designs of the most elaborate character are often seen in tattoo marks, many of them showing some artistic taste and considerable technical skill. The extent to which tattooing has been carried in some individuals has been limited only by the cutaneous surface. In the well-known case of the tattooed man from Burmah, illustrated in Hebra's Atlas, the entire surface was occupied by tattoo marks. Numerous other cases of almost as great extent have been seen.

The usual method of tattooing is first to outline upon the surface the design, and then to prick out this design with a needle or a bundle of needles, and after that to rub in the pigments. For dark blues and blacks, carbon in some form is used, charcoal, lampblack, India ink; other pigments used for various colors are cinnabar, carmine, indigo, Prussian blue. The dangers of tattooing, at the hands of the unskilled persons by whom it is usually practised, are by no means small. All sorts of infections are possible: lymphangitis, erysipelas, chancroid, tetanus, tuberculosis, leprosy, and syphilis. Many cases of syphilis transmitted by this method are recorded in the literature. The means of transmission—by the saliva of the operator, the use of an infected needle, subsequent infection of the unhealed wound—are manifest.

Much ingenuity has been exercised in attempts successfully to remove these marks. The treatment of powder stains and similar stains is largely a matter of mechanical removal, and to be successful this must be done immediately after the production of the marks, before the particles of pigment have become so disintegrated that their mechanical removal is impossible. The individual masses of pigment have to be patiently picked out, for which purpose an iris needle or a small sharp-pointed knife is most convenient. The method requires great patience both on the part of the operator and on that of the patient, but if thoroughly done immediately after the injury it gives satisfactory results. A certain amount of anæsthesia may be obtained by the application of small quantities of weak cocaine solution or by the use of an ointment of ten- to twenty-per-cent. orthoform in lanolin. In connection with the mechanical removal of the particles of pigment, the use of a strong solution of H_2O_2 as a bleaching agent has been suggested, and it is perhaps the best antiseptic for use in these cases; but it is hardly possible that powder stains or coal-dust stains could be bleached by this means, since at the body temperature carbon (which causes most of the discoloration) cannot be bleached with oxygen.

The principle of almost all of the methods for the removal of tattoo marks is their destruction by mechanical means or by the production of a destructive inflammatory process which causes a superficial eschar. Very small stains can be destroyed by the use of the cutaneous punch or by electrolysis or by excision. In using electrolysis the needle attached to the negative pole of a battery with a current of from two to ten milliampères is inserted at various points around the periphery of the marks, and a sufficient reaction is produced to cause the destruction of the involved tissue. In a few days after the application a dry superficial eschar forms, which is thrown off, leaving a white scar. Of course these mechanical methods can only be applied to very small lesions on account of the scars which they produce. The various methods for the treatment of larger lesions depend upon the application of some chemical irritant which sets up an acute inflammatory process sufficiently intense to cause destruction of the superficial layers of the skin. Many irritants have been suggested for this purpose: chromic acid, carbolic acid, acetic acid, tincture of cantharides, potassium nitrate, etc. The two methods of treatment after this principle which have been most definitely worked out are those of Variot and Brault.

Variot's plan of treatment, according to Brocq, is as follows: First, he places on the tattoo marks a concentrated solution of tannin, and tattoos this in. Then a silver-nitrate pencil is rubbed vigorously over the surface. The action of the silver nitrate is allowed to go on for some moments until the surface becomes black from the formation of silver tannate in the superficial layers of the skin. In the next few days a slight inflammatory reaction occurs, and over the surface treated a closely adherent dark crust forms. After the third or fourth day there is no pain except when there is movement of the muscles under a large crust. Occasionally there is a little suppuration under the crusts, but if secondary infection is avoided no severe inflammation occurs. After fourteen or sixteen days the crust comes off spontaneously, the corium and the epidermis underneath have been repaired, and the locality of the mark is recognizable only by a superficial pink cicatrix which gradually becomes of normal color. A couple of months after the operation the scar is hardly noticeable.

In Brault's plan the irritant used is a solution of chloride of zinc, 30 gm., to 40 gm. of water. The mark is tattooed with needles dipped in this solution, and in addition the surface is lightly moistened with the same solution after the tattooing. A mild inflammatory reaction is produced, followed by the formation of a crust which subsequently exfoliates, leaving a pinkish, slightly scarred surface similar to that after Variot's operation.

In the use of either of these methods several attempts may be necessary. The surface treated at one time should not exceed one or two square inches, and of course ordinary surgical precautions as regards the cleanliness of the surface, both before the operation and during the subsidence of the inflammatory process, should be observed. Both of these methods are founded upon correct pathology and are worthy of trial. Variot's method would seem the one of preference, as the action of silver nitrate can be more accurately controlled than that of zinc chloride.

Ohmann-Dumesnil has proposed a method of removing these marks by digesting with digestive ferment the connective tissue which encapsulates the pigment particles and thus liberating them, so that they can be carried away by the lymphatics. For this purpose he uses glycerole of papoid or of caroid. His method is as follows: The skin is made surgically clean and then anæsthetized with a spray of ethyl chloride. The surface is then covered with glycerole of papoid or of caroid and tattooed with a bunch of six to ten very fine needles which have been dipped in the solution. The tattooing should be firmly done, but the needles should be driven in just far enough to draw the least possible blood. Glycerole of papoid or of caroid is then poured over the area and it is covered with gauze. On the removal of this after two or three days the tattoo marks present a hazy appearance. Shortly after, a crust forms which later falls off, and with it the marks disappear. If any trace remains the process is to be repeated. This idea is ingenious, but the results have not been satisfactory in the hands of some workers. It is questionable whether the results obtained are not those due simply to a destructive inflammatory process, as in the other methods.

William Allen Pusey.

TEA.—(*Thé*, Codex Med.) The prepared and dried leaves of *Thea sinensis* L. (*Camellia Thea* Link, etc. Fam. *Theaceæ*). This definition includes, as varieties, *Thea* (*Camellia*) *viridis*, *T. Bohea*, and others, as well as the wild Assam tea tree, supposed to be the origin of them all. The tea plant as seen under cultivation is a shrub, a metre or so in height (from two to five feet), but in the wild state it becomes a small tree of from five to ten metres. The leaves are alternate, evergreen, rather thick and leathery, smooth when mature, short-petioled, lanceolate, of varying bluntness, serrate, feather-veined, the veins not reaching the margins, and from 5 to 10 cm., or in the much larger wild plant, from 15 to 20 cm. long (Fig. 4596).

Tea is a native of Asia, and grows in a semi-wild state in many of the districts where it is cultivated, but has only been found in an unquestionably indigenous condition in Assam, where it was discovered, some fifty years ago, by Mr. Robert Bruce, as a good sized tree with very large leaves. It is now cultivated in many parts of the world; first in importance in China, where it is said to have been domesticated more than a thousand years ago, also in great quantity in Japan, Java, and India, to a slight extent in South America and elsewhere, and finally in the United States, experimentally. Although it grows pretty well in many places and is comparatively hardy, the higher price of labor is a bar to its profitable production in most civilized countries.

The earliest knowledge of the use of tea is from the Chinese, to whom it was familiar one thousand and perhaps two thousand years ago. It was introduced into Japan in the thirteenth century A.D., and into Java and India in recent times. It was first used in Europe near the middle of the seventeenth century.

Tea is planted in gardens and tended without gathering until two or three years old; then the leaves and buds are plucked for two or three successive crops each season. If green tea is to be made, they are immediately dried over a heated stove, and afterward colored more or less. For black tea the leaves are pressed in little heaps, and allowed to wilt and ferment a little before drying, which

FIG. 4596.—Tea Plant, Flowering Branch. (Baillon.)

is effected in the same way as above; by this process some of the tannin is decomposed, and the essential oil altered so as to modify the taste and smell a little; its color is also very much darkened, as well as that of the infusion made from it. The principal varieties of tea are: Black—flowery pekoe, orange pekoe, souchong, congou, bohea, etc. Green—gunpowder, imperial, hyson, young hyson, etc. The teas of our market are nearly always "blends," made by mixing several grades together.

The usual shape of tea is attained by compressing and rolling the leaves in the hand or upon a table until they are crumpled into the little rolls or wads of which commercial tea consists; in the nicer sorts each leaf is rolled by itself.

COMPOSITION.—In the proportions of the ingredients there is considerable variation, but the following are the principal ones: *Essential oil* from one-half to one per cent., which is the source of its flavor; *caffeine* (theine) from one-half to two or three per cent., which gives it bitterness. This alkaloid is found in half a dozen other plants, most of which are used somewhere as stimulating food adjuncts (see *Caffeine, Guarana, Cola Nuts*, etc.). It is also related to cocaine and theobroma. The amount of *tannin* in tea is large (from twelve to seventeen per cent.).

ACTION AND USE.—The large amount of tannin found in tea makes it an active astringent, especially to those unaccustomed to its use. It constipates the bowels, impairs the digestion, and reduces intestinal secretion when taken in large quantity; locally it makes tea a mild hæmostatic, and a useful wash for indolent ulcers, exuberant granulations, etc. The essential oil gives to tea its agreeable flavor and a good part of its exhilarating character; it relieves fatigue, stimulates thought, postpones sleepiness, and cheers the mind. The *caffeine* is the chief mental and nervous stimulant and cardiac tonic element. By long-continued, habitual use neither of the above effects is much felt, unless carried to the extent of diminishing the appetite and developing dyspeptic troubles.

The least desirable of the constituents of tea is the *tannin;* it is also one of the slowest to dissolve out, and can, therefore, with a little care, be largely left with the dregs. The quicker an infusion of tea is made, the more fragrance and less bitterness and astringency it has; and the more slowly, the more tannin. Tea for drinking should be made by pouring *boiling* water into a suitable vessel containing the tea and allowing it to stand for from five to ten minutes, no longer. A better way is to rinse the cup in boiling or very hot water until it is heated through, then put in a teaspoonful of dry tea, fill the cup with boiling water, and allow to stand a few minutes. Tea should never be boiled or stand long unless the *tannin* is wanted. If made in an iron vessel or in a tin one which has begun to wear, it will become dark from the formation of a bitter tannate of iron. On account of its almost universal use over the entire world, tea is not often available as a medicine; its effects are identical with those of coffee, but perhaps more astringent and less stimulating than that article. As is the case with coffee, the commercial value of tea depends more upon its aroma than on the amount of caffeine it contains.

ALLIED PLANTS.—There are a dozen or more species of *Thea,* one of which is *Thea Japonica,* the beautiful camellia of the gardens. Besides this there is nothing of economic importance in the order. *W. P. Bolles.*

TEETH.—ANATOMY.—The teeth are commonly divided into two sets, according to the period of their eruption. The teeth which erupt first are variously designated as the deciduous, the temporary, the milk, or the primary teeth. The teeth erupting subsequently to the first set are called the permanent or secondary teeth. In addition to these there are supernumerary teeth, which usually occur in connection with the permanent, but may, in rare instances, be found with the temporary teeth; and there are so-called third dentitions, the genuineness of which, though fairly well established, is not without question.

The permanent teeth are thirty-two in number, sixteen being placed in the upper, and sixteen in the lower, jaw.

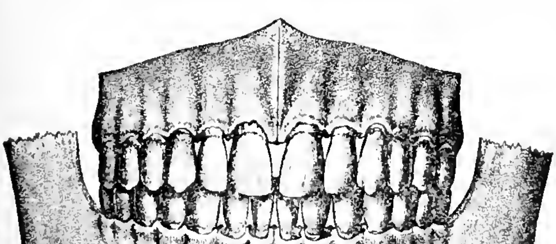

FIG. 4597.—The Permanent Teeth, natural size, showing their Method of Arrangement and Articulation. (Carabelli.)

In each jaw there are four incisors (two central and two lateral), two canines, four bicuspids, and six molars.

A formula to express the number of the various teeth in each jaw is written as follows: I $\frac{4}{4}$, C $\frac{2}{2}$, Bic. $\frac{4}{4}$, molars $\frac{6}{6}$ = 32.

The teeth of the upper jaw are symmetrically arranged along the alveolar margin of the superior maxillary bones. When viewed from below, their crowns are found to describe a parabolic curve. This curve, however, varies according to nationality, heredity, and accidental circumstances. The teeth of the lower jaw are ar-

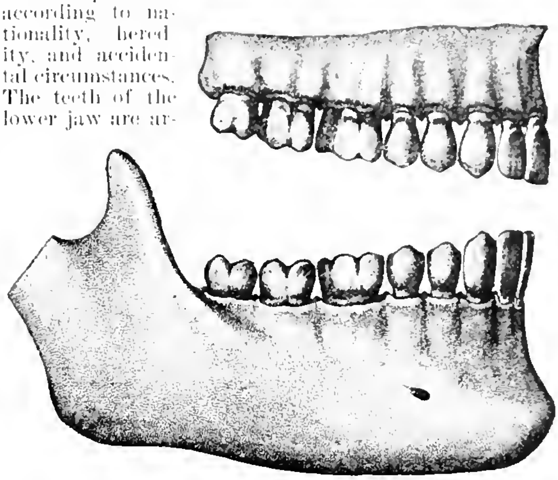

FIG. 4598.—The Permanent Teeth, natural size, showing the Curves in the Alignment of the Crowns. (Carabelli.)

ranged along the alveolar margin of the inferior maxillary bone, and their crowns describe a curve similar to that found in the upper jaw. This curve, however, is more pointed in front and more divergent behind. Speaking roughly, the masticating surfaces of the teeth of each jaw lie in a single plane, no crown projecting in a marked way beyond its neighbor. The teeth, also, when normally arranged, show no gap in the row, each tooth thus by its position giving and receiving support. In both these respects human teeth contrast strongly with those of the lower animals. In these it is common to find that certain teeth, as the canines in the carnivora, present a marked elongation, and also that between the teeth there occur intervals which allow of their interlocking.

The curve on which the upper teeth of the permanent set are arranged is normally somewhat larger than that of the lower teeth. In consequence, the anterior superior teeth overlap the anterior inferior teeth, as do also to a slight extent the superior bicuspids and first and second molars the corresponding lower teeth. The wisdom teeth, however, meet practically edge to edge. It is to be further noted that the superior teeth are not situated directly opposite corresponding inferior teeth. The superior centrals are opposite the inferior centrals and a portion of the inferior laterals; the superior laterals are opposite a part of the inferior laterals and a part of the inferior canines; the superior canine occludes between the inferior canine and the first inferior bicuspid; the first superior bicuspid occludes between the first and the second inferior bicuspids; the second superior bicuspid occludes between the second inferior bicuspid and the first molar; the first superior molar occludes with the first and the anterior portion of the second inferior molar; the second superior molar occludes with the second and the anterior part of the third inferior molar; the third superior molar occludes with the third inferior molar, and is the only tooth in the upper jaw having a single antagonist. While it has been stated that the masticating surfaces of the teeth of the upper and lower jaws are on a single plane, yet slight deviations from this rule are to be noticed. If we follow the lower edge of the upper teeth from a superior central around to the wisdom, we shall find that the line ascends gently from the central to the interval between the first and second bicuspids, then descends till past the first molar, when it ascends slightly to the end of the row. On the lower jaw the anterior teeth are slightly elevated above the posterior, and between the canine and the wisdom tooth a slight concavity is to be observed.

In its description a tooth is to be divided into a crown, a root or fang, and a neck. The crown of a tooth is that part which normally appears beyond the margin of the gum. The root or fang is that part which is normally embedded in the alveolus of the maxillary bone. The neck is a more or less constricted belt lying at the margin of the gum where the crown joins the root. The surfaces of the crowns are thus designated. Those surfaces lying adjacent to the lips are called labial surfaces, those lying adjacent to the buccinator muscle are called buccal surfaces. Those surfaces on the inner side of the teeth lying adjacent to the tongue are called lingual surfaces. In the case of the upper bicuspids and molars, however, such surfaces are more commonly called palatal surfaces, from their relation to the hard palate. The grinding surface of the bicuspids and molars is called the coronal surface. The surfaces between adjoining teeth are called approximal surfaces, and are divided into two classes—mesial and distal. The mesial approximal surface of a given tooth is that surface which, were the row of teeth in a straight line, would face toward a line drawn between the central incisors. The distal approximal surface is the corresponding surface at the opposite side of the tooth. These names are, as a rule, applied to the crowns of the teeth, though they are, with the exception of the term coronal, used also in connection with the roots.

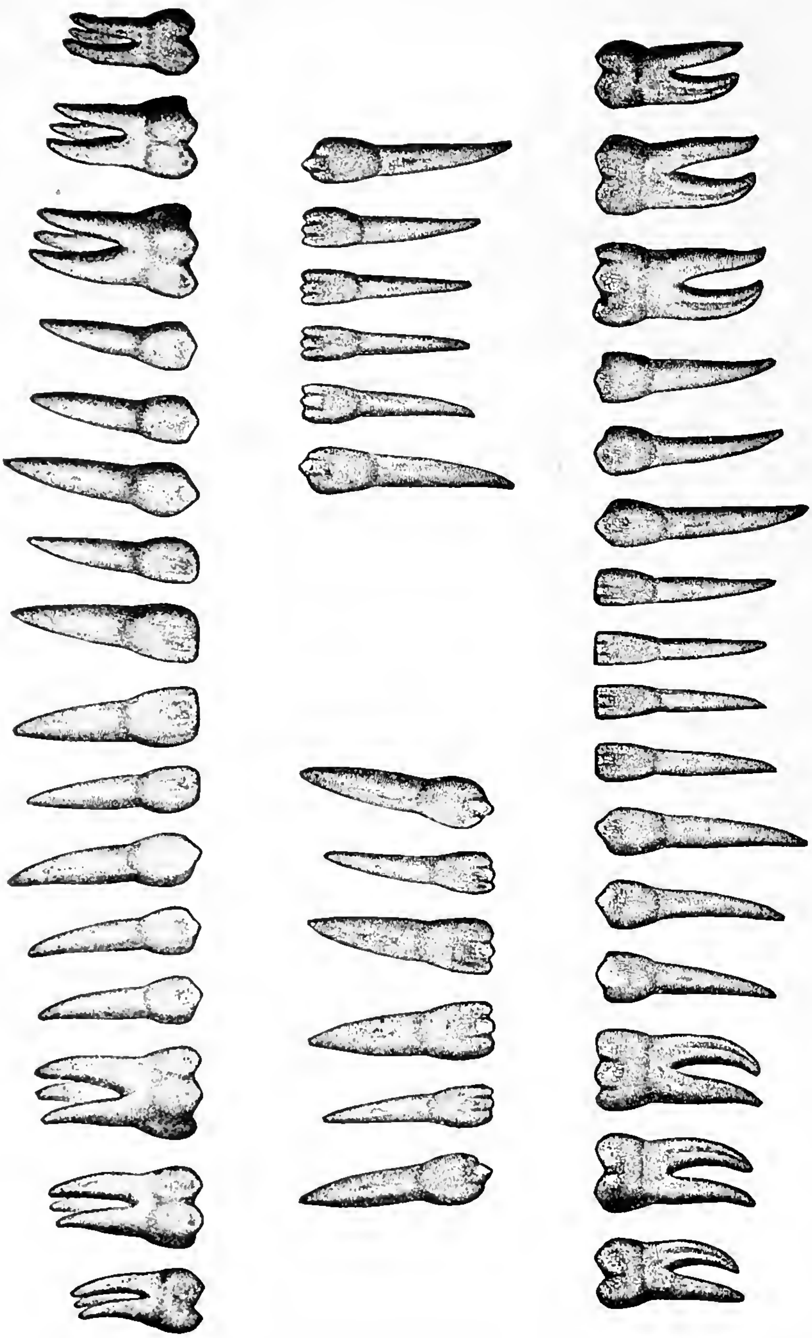

Fig. 4590.—The Permanent Teeth (slightly reduced in size), showing the Labial and Buccal Surfaces. The middle row of teeth represents freshly erupted incisors and canines, with the tubercles on their cutting edges intact. (Carabelli.)

The *temporary teeth* are twenty in number. In each jaw there are four incisors, two canines, and four molars. The dental formula is I $\frac{4}{4}$, C $\frac{2}{2}$, molars $\frac{4}{4}$ = 20.

This formula differs from that of the permanent teeth by the entire absence of bicuspids, and by the loss of four molars. The temporary teeth can best be described by comparing them with the permanent teeth, which they closely resemble.

The incisors and canines of the upper and under jaws are very much smaller than the corresponding teeth in the permanent set, and the root of the upper central incisors is somewhat curved on the mesial side where the corresponding root in the permanent teeth is practically straight.

The first upper molar is situated behind the canine, and in appearance is a compromise between a bicuspid and a molar. Its crown resembles in general shape that of an upper molar, but is quite small, and bears only three cusps—two external and one internal. The roots are three in number, resembling in shape and position those of the permanent molars. They are, however, more divergent, thus providing room for the first bicuspid, whose crown is situated directly beneath the temporary tooth, and within the grasp of its roots.

The second upper molar is a much larger tooth than the first, and resembles so closely the first permanent molar that it might be mistaken for it. Its roots are more divergent, however, in order to embrace the crown of the second bicuspid, to which it gives way in the permanent dentition.

The first molar in the lower jaw is situated behind the canine, and resembles in shape a permanent molar of the lower jaw. Its crown is surmounted by four cusps—two external and two internal. It has two roots, one anterior and one posterior, between which is developed the crown of the first inferior bicuspid.

The second lower molar is larger than the first, and a little smaller than a permanent lower molar, which it

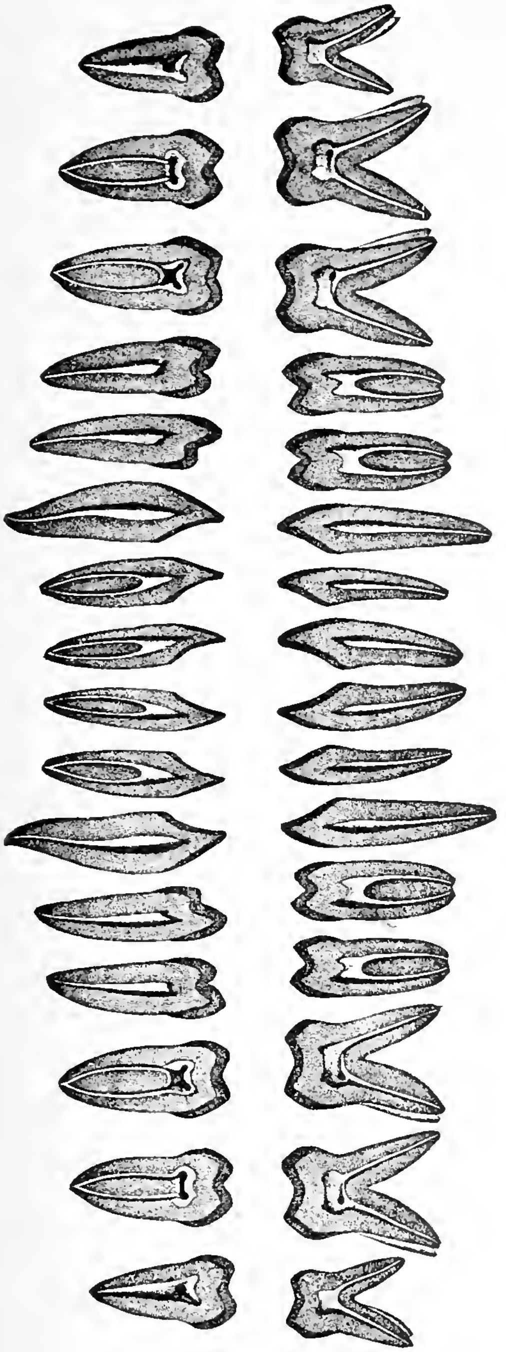

FIG. 4600.—The Permanent Teeth, natural size; a Section through the Pulp Cavity, showing its Size and Shape. (Carabelli.)

closely resembles. Its crown has five cusps—three external and two internal. There are two roots, one anterior and one posterior, which embrace the developing crown of the second lower bicuspid. It is characteristic of the temporary teeth that the foramen at the apex of the roots is larger, that the necks of the teeth are more constricted, and the color whiter and more delicate than in the permanent teeth; also, that the six anterior upper teeth do not overlap the corresponding lower teeth to such an extent as in the permanent set.

MICROSCOPIC ANATOMY OF THE TEETH.—A longitudinal section through a tooth will reveal four distinct structures—the enamel, the cement, the dentine, and the pulp. The pulp is a soft mass of connective tissue richly supplied with blood-vessels and nerves, and located in the centre of the tooth. It fills the pulp cavity. The pulp cavity starts at the apex of the root or roots, as the case may be, as a thread-like canal, and gradually enlarges till it reaches the crown, where it attains its greatest size; throughout its whole course it imitates in shape the external contour of the tooth. An artery and nerve, and sometimes more than one of each, enter the apical foramen of each root of a tooth, and, branching freely, distribute themselves to all parts of the pulp, being especially abundant about its periphery. A venous system returns the blood through the apical foramen into the general circulation. It is a matter of dispute whether a lymphatic system is present or not; most observers consider that it is not. Around the periphery of the pulp, and distinct from the connective-tissue cells forming its body, there exists a layer of cells called the odontoblastic layer, or the membrana eboris. In shape these cells are large in comparison with the connective-tissue cells; they are of columnar form and have several processes. By these processes they are in close relation with the terminal filaments of the nerve of the pulp, joined to one another, and connected with the dentinal fibrils.

Immediately surrounding the pulp comes the dentine, which is the most abundant tissue of the tooth. It is

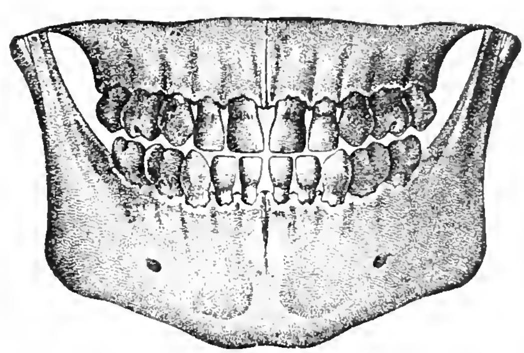

FIG. 4601.—The Temporary Teeth, natural size, showing their Arrangement in the Maxillary Bones, and Relations to one Another. (Carabelli.)

hard and dense in structure, of a yellowish-white color and silky lustre. On analysis it is found to contain animal matter, twenty-eight per cent.; earthy matter, seventy-two per cent. Its various components are thus given by von Bibra:

	Per Cent.
Organic matter	28.01
Phosphate and fluoride of calcium	66.72
Carbonate of calcium	3.36
Phosphate of magnesium	1.18
Other salts	.73
Total	100.00

Morphologically considered, it is composed of a structureless matrix permeated by countless tubules, each tubule possessing a lining membrane and a central fibril. The tubules start from the pulp cavity, where they have a diameter of about $\frac{1}{5000}$ of an inch, and radiate toward the periphery of the dentine, becoming smaller and more numerous as they advance. While the direction taken by the tubules in different parts of the tooth varies greatly, yet contiguous tubules are essentially parallel. Two or three undulatory curves are to be noticed in the length of a tubule, and the name primary curvature has been attached to them. Numerous spiral turns occurring in the course of the undulatory curves have been named the secondary curvatures. The tubules give off

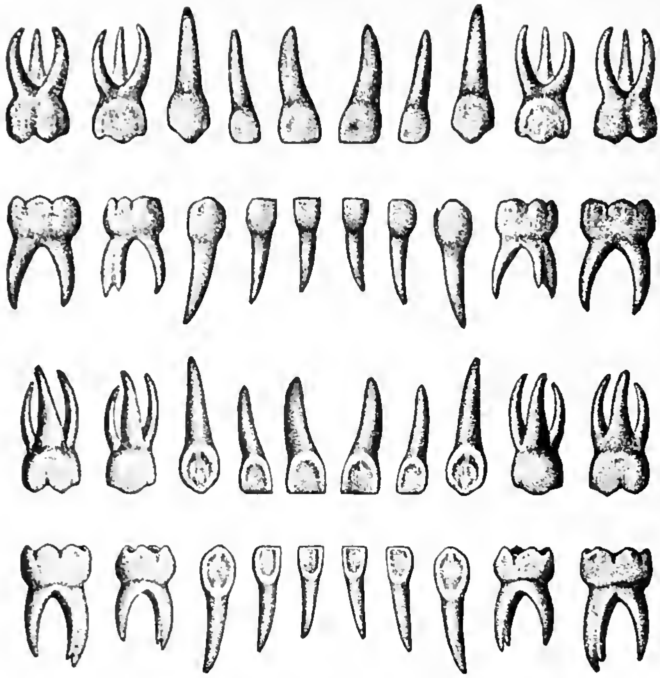

FIG. 4602.—The Temporary Teeth, natural size, showing the External and Internal Surfaces. (Carabelli.)

frequent branches throughout their entire length. Some of these branches are important, extending to the outer layers of the dentine parallel to the main channel. Other branches serve merely to connect one tubule with another, and still others are blind processes. At the outer layer of the dentine the tubules become diminished in size and very numerous. Some of the tubules can be seen entering the granular layer of the dentine, while others either terminate blindly or anastomose with neighboring tubules. The "granular layer of Purkinje" consists of numerous irregular cavities filled with cells having nuclei, and forming a layer about the peripheral portion of the dentine, being especially well developed where the dentine is covered by the cement of the root. The cavities of this layer communicate with each other, and in some cases with the canaliculi of the cement, besides being connected with the tubules of the dentine.

FIG. 4603.—An Upper Temporary Molar, with a Bicuspid within the Grasp of its Roots. (Weil.)

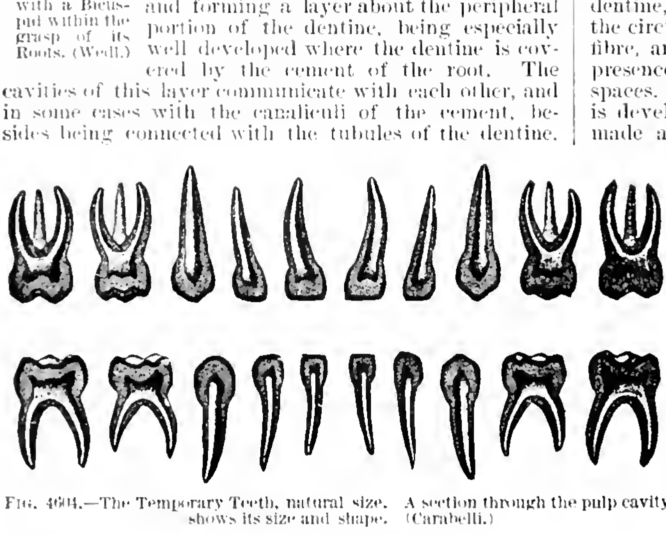

FIG. 4604.—The Temporary Teeth, natural size. A section through the pulp cavity shows its size and shape. (Carabelli.)

The tubules of the dentine have been shown to possess a lining membrane, and to this the name dentinal sheath has been applied. This structure resists the action of reagents which destroy the matrix in which the tubules are embedded, and is supposed to consist of elastic tissue, though its composition is not surely determined. The dentinal fibril which occupies the centre of the tubule is a soft homogeneous substance, having a nerve-like function, but lacking true nerve structure.

The fibril is connected at one end with an odontoblastic cell in the periphery of the pulp, and the other end enters, in many cases at least, the granular layer of the dentine, coming into contact with the soft tissue therein contained. Through the dentinal fibril communication is maintained with the nerves of the pulp, and sensation is supplied to all parts of the dentine. In longitudinal section of that part of the dentine which lies in the crown of the tooth are to be seen lines which are called the "incremental lines of Salter." They run, in general, parallel to the external contour of the crown, and mark stages in the development of the dentine, being not unlike the circular rings of wood fibre, and are due to the presence of interglobular spaces. That the dentine is developed by stages is made apparent by treating it with hot caustic potash. By this reagent the dentine becomes separated into layers, which cross the tubuli at right angles, and are concentric about the pulp. In the crown of the tooth, between one layer of dentine and another, there occur imperfectly calcified spots where

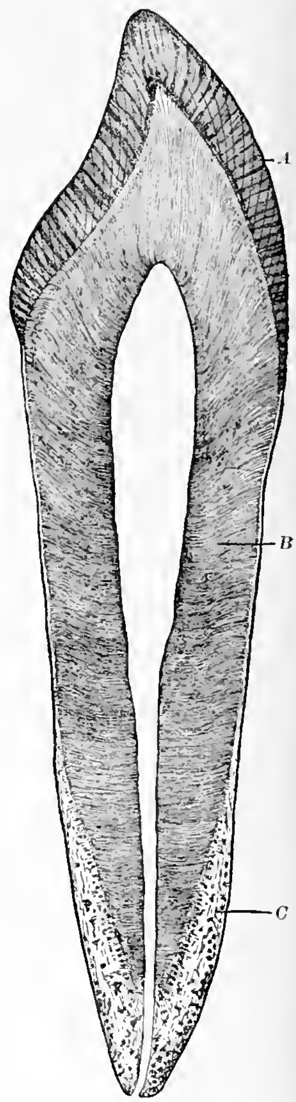

FIG. 4605.—A Microscopic Section of a Canine Tooth, showing, *A*, the enamel, with its enamel rods running from the dentine to the outer surface. The dark strips indicate places where the enamel rods cross each other. The fine parallel lines are the "brown lines of Retzius." *B* is the dentine, with its tubules radiating from the pulp cavity. The undulatory curves of the tubules are called the primary curvatures. The secondary curvatures are not visible at this enlargement. The granular layer is indicated by the dotted line about the periphery. It is especially marked between the cement and dentine, and practically absent between the enamel and dentine. The interglobular spaces are represented in the coronal portion of the dentine just removed from the junction of the dentine and enamel. *C* indicates the cement, with its lacunæ and canaliculi.

the dentine assumes a globular form, and where irregular interglobular spaces are found. Series of minute interglobular spaces give rise to the "incremental lines of Salter."

The dentine is surrounded in the crown by the enamel, and in the root by the cementum.

The cementum, or crusta petrosa, is the outer covering of the root. It is thinnest at the neck of the tooth, where it meets and slightly overlaps the enamel, and grows gradually thicker toward the apex, about which point it is most abundant and its structure is most perfectly developed. Cement has essentially bone structure; it possesses lacunæ and canaliculi, but has normally no Haversian canals. The lacunæ and canaliculi are wanting or rare in that part of the cement near the neck of the tooth, but about the apex of the root they are numerous and well developed. The lacunæ lie in parallel planes encircling the pulp cavity, their canaliculi anastomose freely with each other, and in some cases they connect with the granular layer of the dentine, thus establishing a communication between the lacunæ of the cement and the pulp of the tooth through the granular layer and tubuli of the dentine.

Immediately surrounding the cementum of the root exists the peridental membrane, which is identical with the periosteum which lines the bone forming the socket of the tooth. The peridental membrane serves a triple function. It nourishes the bone of the socket and the cement of the root, besides forming a bond of union between the root and its socket. The peridental membrane, like all periosteum, is composed of connective tissue richly supplied with blood-vessels. The arterial supply comes from capillaries of the gum about the neck of the tooth, from the deep substance of the bony socket, and from a branch of the artery entering the apical foramen of the tooth.

The enamel forms the outer covering of the crown; it is the hardest structure in the body. It resembles den-

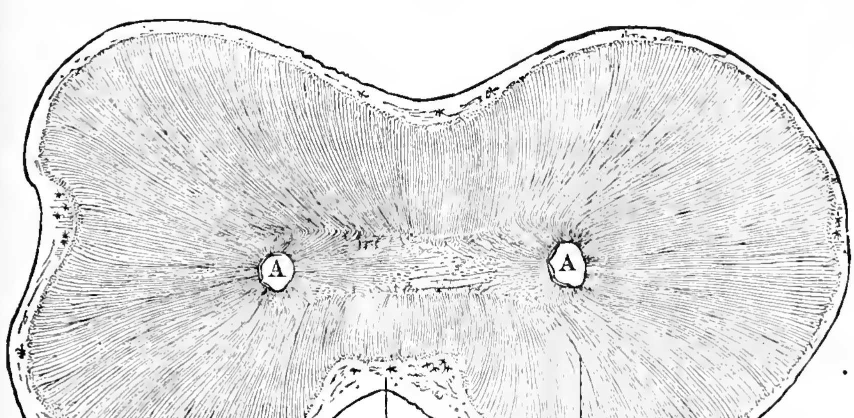

FIG. 4606.—Cross-section of an Upper Bicuspid Tooth. A, A, The root canals; B, the granular layer of the dentine; C, the cementum, showing occasional lacunæ; D, the dentine.

tine in its chemical constituents, but has a much greater proportion of inorganic material. The following analysis is given by von Bibra:

	Per Cent.
Phosphate and fluoride of calcium	89.82
Carbonate of calcium	4.37
Phosphate of magnesium	1.34
Other salts	.88
Cartilage	3.39
Fat	.20
Total	100.00

The proportion of organic and inorganic matter is as follows.

	Per Cent.
Organic	3.5
Inorganic	96.5
Total	100.00

Morphologically considered, enamel is composed of rod like, hexagonal prisms, arranged side by side, one end of the prism resting on the outer layer of the dentine and the other forming the free surface of the crown of the tooth. Each prism extends, as a rule, through the entire thickness of the enamel. There are some, however, which extend only from the centre of the enamel to its free surface, thus preventing gaps which would otherwise occur, the outer surface of the enamel being of greater extent than the inner. In diameter the enamel prisms measure $\frac{1}{7000}$ to $\frac{1}{5000}$ of an inch. Each prism, when isolated, has slight varicosities and presents a striped appearance similar to muscular fibre. The prisms run, in general, parallel to each other, and in a wavy course; their inner ends are implanted in slight hexagonal depressions in the surface of the dentine, and their outer ends are received into similar depressions in the under side of the cuticle of the enamel when the cuticle is present. A vertical section of the enamel shows that it is thickest in the crown, especially in the region of the cusps, and becomes thinnest at the neck of the tooth, where it is overlapped by the cement of the root. The enamel prisms are seen to leave the outer surface of the dentine at right angles, and radiate toward the external surface of the tooth. The general yellowish-white color of the enamel is varied by dark bands extending vertically from the dentine to the free surface of the enamel, caused by the crossing of bundles of enamel prisms. Certain delicate lines running longitudinally through the substance of the enamel are also to be noticed. These are called the "brown lines of Retzins," but it is not known to what they are due. Also between enamel rods, usually near the surface of the dentine, are

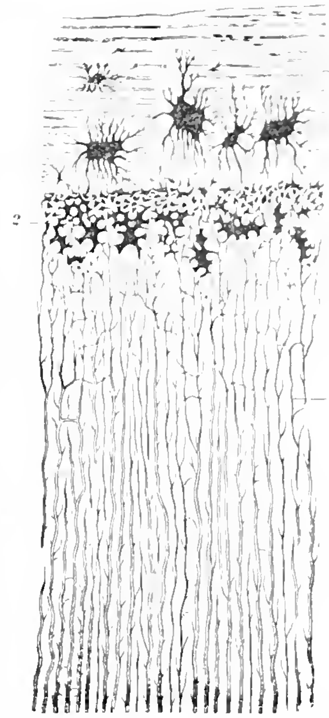

FIG. 4607.—A Section of Dentine and Cement. The figure 1 represents the cement with its lacunæ and canaliculi; the figure 2 represents the granular layer of the dentine. It is to be noticed that the lacunæ communicate with the cells of the granular layer. The figure 3 represents the tubuli of the dentine, showing their diminution in size as they go toward the cement, also their frequent anastomoses and their connection, in some cases, with the cells of the granular layer. (Quain.)

found irregular cavities due to an imperfect calcification of the enamel. On cross-section the enamel has the appearance of a mosaic pavement, each prism showing its hexagonal shape.

The cuticle of the enamel, or Nasmyth's membrane, is to be found in a freshly erupted tooth. It consists of

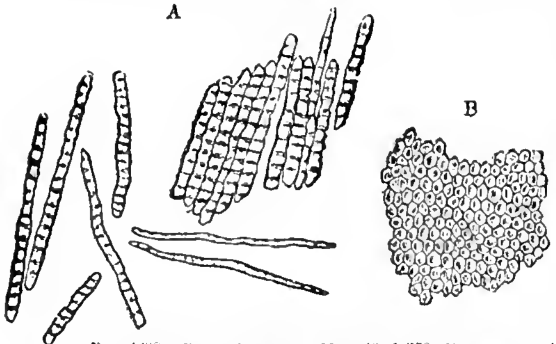

FIG. 4608.—Enamel Prisms. Magnified 350 diameters. *A* shows the varicosities and striations of the prisms; *B* is a cross-section of enamel, showing the hexagonal shape of the prisms, and their tessellated appearance. (Quain.)

a delicate epithelial covering which encloses the enamel; it is, however, so delicate that in the slightest use it is worn away. It receives in hexagonal depressions on its under side the outer ends of the enamel prisms.

TIME OF ERUPTION OF THE TEETH.—The first dentition begins about the seventh month, and is completed about the twenty-fourth month. The second dentition begins about the sixth year, and is completed about the twenty-first. Considerable variation exists in the time at which individual teeth erupt, and no date can be absolutely fixed for the appearance of a given tooth. It is possible, however, to state the time when the eruption of a tooth is normally to be expected, and the following tables are appended:

Temporary Teeth.

The central incisor erupts at the	7th month.
The lateral incisor erupts at the	9th month.
The first molar erupts at the	12th month.
The canine erupts at the	18th month.
The second molar erupts at the	24th month.

Permanent Teeth.

The first molar erupts at the	6th year.
The central incisor erupts at the	7th year.
The lateral incisor erupts at the	8th year.
The first bicuspid erupts at the	9th year.
The second bicuspid erupts at the	10th year.
The canine erupts at the	11th year.
The second molar erupts at the	12th year.
The third molar erupts at the	17th to 21st year.

As a rule, in both the first and second dentitions the lower teeth erupt before corresponding teeth in the upper jaw.

PHYSIOLOGY OF THE TEETH.—Under this head we naturally consider the purposes for which teeth exist, and how they perform their several functions. The subject may be divided into three heads:

(1) The function of the teeth in facial expression. (2) The function of the teeth in mastication. (3) The function of the teeth in articulation

The importance of the teeth in facial expression becomes apparent when we consider the effect of their absence, as shown in aged people. In such the lower part of the face has lost the round and graceful lines of early years; the chin is pointed, and approximates the end of the nose; the lips are retracted and flabby, and a characteristic hollow extends along the cheek. When present, each tooth aids in sustaining the proper proportions of the face. The upper front teeth, by being slightly in advance of the lower, produce that slight projection of the upper lip beyond the lower, found in normally shaped features. The bicuspids and molars, by their apposition, fix the relation of the lower to the upper jaw, and by their bulk give fulness to the cheeks. The bony alveolus, also, in which the teeth are embedded, has an important relation to facial expression, for when a tooth has been lost its bony support, being no longer needed, is absorbed, and thus the features are still further deprived of support.

The function of the teeth in mastication is the most obvious and important. Standing as they do at the entrance to the digestive tract, it is their duty to seize upon food, sever its connection with its surroundings, and comminute it so that it can be acted upon readily by the various digestive fluids. The act of seizing and cutting is performed by the six anterior teeth, whose edges, by the protrusion of the lower jaw, are brought opposite to each other. When once a morsel of food has been detached by the anterior teeth, it is passed backward by the tongue and cheeks, to be operated upon by the bicuspids and molars. The bicuspids are fitted both to cut and to grind. They cut by the outer cusps of opposing teeth meeting and passing each other like the blades of a pair of scissors. They crush by a lateral motion, the crowns of the lower bicuspids moving across those of the upper. The function of the molar teeth is to crush and grind, for which purpose they are fitted by their broad crowns. They crush by means of an up-and-down movement, and grind by a lateral movement.

FIG. 4609.—The first profile represents the features undisturbed by loss of teeth. The second represents the edentulous condition, in which the lips fall in and the chin becomes pointed and inclined toward the nose.

The function of the teeth in articulation is best understood by a brief survey of the mechanism of speech. This mechanism includes the vocal cords, and a resonant cavity above the cords, formed by the pharynx and the oral and nasal cavities. This resonant cavity reinforces and modifies sounds made by the vocal cords. Articulation is concerned with sounds of two kinds—vowels and consonants. The vowels are musical notes formed by the vocal cords, and given quality or timbre by the size and shape of the air column in the resonant cavities above. The consonants are sounds produced by the same mechanism, but due to irregular vibrations, and hence are noises. The oral cavity, being able to change its size and shape in numberless ways, is the most important agent in sound modification.

To produce articulate sounds the column of air must be obstructed and forced into channels of definite size and shape. The column of air is obstructed in three ways: first, by applying the back of the tongue to the palate; second, by applying the tip of the tongue to the posterior surfaces of the anterior teeth; and third, by a closure of the lips. It is forced into definite channels by pressing the tongue against different parts of the roof of the mouth, and against the inner surface of the upper teeth.

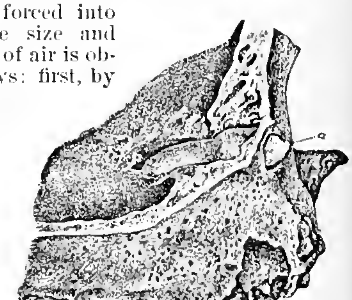

FIG. 4610.—Illustrates the Impaction of a Right Superior Lateral (*a*), which lies in the superior maxillary bone at right angles to its normal position. (Wedl.)

PATHOLOGY OF THE TEETH.—*Pathology in the Number of Dentitions and their Time.*—While two is the normal number of dentitions, much can be heard and read of a third dentition, the authority for which, however, rests, as a rule, with unscientific observers, and is of very little value.

The entire absence of one or both of the normal dentitions is an established fact; such cases, however, are decidedly rare, especially those in which neither dentition has occurred. There is usually associated with this condition a failure in the growth of hair throughout the body. The condition of the alveolar ridge in such cases is similar to that which ensues on the extraction of the permanent teeth. Artificial substitutes, however, are not always necessary, inasmuch as the gum, in such cases, is very tough, and capable of performing with remarkable facility the duties of mastication.

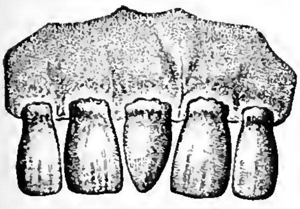

FIG. 4611.—A Conical Supernumerary Tooth Located between the Superior Central Incisors. (Carabelli.)

Pathology in the Time of Dentition.—The deciduous teeth are in rare instances erupted at birth. When deciduous teeth are delayed in their eruption it is commonly due to rickets. A delay in the eruption of the permanent teeth is also frequently noticed. An important cause for this delay is the prolonged retention of the deciduous teeth, an obstacle being thus present which prevents the permanent teeth from taking their place. Cases are on record of deciduous teeth persisting till middle or old age. It often happens, however, that a permanent tooth is kept from eruption because its place has been taken by another permanent tooth which had an earlier start, and which has occupied all the available room. This is especially liable to happen with the superior canines, on account of their coming to the surface after the lateral and the first bicuspid have taken their place in the arch. If, as often happens, the temporary canine has been prematurely extracted, allowing the adjoining teeth to close in the gap, or if the arch is unusually narrow, or the teeth unusually large—and sometimes the two latter conditions exist together—then the canine is likely to be crowded out beyond the arch or to be imprisoned in the alveolus. The canine may be permanently imprisoned, or until the extraction of a bicuspid or lateral incisor offers it a chance to erupt.

The wisdom teeth are always very liable to detention within the jaw, and their eruption may be either prevented or long delayed. This happens from causes similar to those just described with regard to the canine. The modern civilized jaw seems to be made too short to contain a full complement of developed teeth, and, as the wisdom teeth come last, they, though of stunted size, are frequently unable to enter the arch. Imprisoned or partly erupted wisdom teeth, especially of the lower jaw, may cause very serious symptoms, both local and reflex. The local symptoms consist of pain and swelling in the vicinity of the tooth; the reflex symptoms of neuralgias about the head, and a tonic contraction of the muscles which close the jaw. In some cases an abscess may be formed which, if lacking prompt exit, may open by fistula on the outside of the face, at the angle of the jaw, or in the neck, or even as low down as the subclavicular region. Imprisoned canine and incisor teeth are sometimes found far from their normal position. Cases are cited in which the crown of the superior canine has penetrated the nasal cavity and the antrum; they have also been located in the palatine portion of the superior maxillary bone. Lower canines have been found with their long axes parallel to the body of the jaw, at or near the tips of the roots of the inferior lateral and bicuspids. The superior lateral may be delayed in its eruption, or imprisoned for want of room in the arch, and may in consequence take abnormal positions similar to those taken by the superior canine.

Pathology in the Number of Teeth in a given Dentition.—In connection with both the first and second dentitions we find at times both an excess and also a deficiency of teeth. Teeth in excess of the normal are called supernumerary teeth. Such may be coincident in time of eruption with the teeth in whose neighborhood they appear, or they may precede or follow. Supernumerary teeth are divided into two main classes—teeth whose form differs from that of normal teeth (conical teeth), and teeth whose form resembles that of normal teeth. Supernumerary teeth are not common in connection with the first dentition; when they occur they are found more frequently in the lower jaw, and belong in shape to the second class, inasmuch as they resemble the teeth with which they are associated. The duplicate tooth is usually a lower incisor, and it takes its place regularly in the arch, being erupted at about the same time as its companion incisor. Supernumerary teeth are more frequently found in connection with the second dentition, and are usually located in the upper jaw.

They as a rule make their appearance just after the adjoining tooth is erupted. Conical supernumerary teeth are the most common kind. They have the same structure as normal teeth, but in shape resemble a diminutive cuspid. Their crown, however, has not the angular outline belonging to that tooth, but is cone-shaped, as their name implies. The root is round and tapering. These teeth occur most frequently in connection with the superior incisors. One may be located between the two centrals in the arch, or between the central and the lateral. They may be placed without the arch, on either its labial or palatal side. Conical teeth are not commonly found adjoining the molars, bicuspids, or cuspids, though they may exceptionally be found in all these localities. If found outside the arch, conical teeth are of no value and should be extracted; if found in the arch, it often becomes a question whether their presence or absence produces the greater deformity. Supernumerary teeth which resemble normal teeth are generally found among the upper incisors and regularly placed in the arch; they do not necessarily produce deformity, and by the unprofessional eye would not be noticed. A supernumerary superior lateral is most commonly found; next in frequency comes the superior central, while duplicates of the superior molars, bicuspids, and canines are rare. Carl Wedl, in his "Pathology of the Teeth," gives a drawing of the superior and inferior maxillæ of a negro, in which appear four molars on each side of both the upper and under jaw, besides an extra bicuspid in the lower jaw, making five supernumerary teeth in all; the molars are all in the dental arch, but the bicuspid is situated at the inner side of its neighboring bicuspid. A third kind of supernumerary tooth, sometimes described, is called the cubic-crowned tooth; it resembles in shape the lower bicuspid, and occurs in the anterior part of the mouth behind the superior incisors.

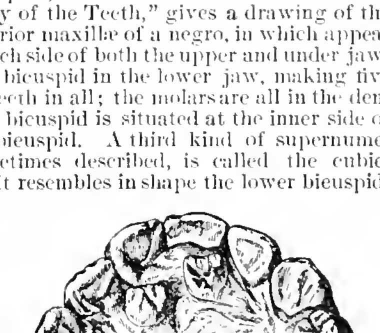

FIG. 4612.—Shows Two Cubic-crowned Supernumerary Teeth, Occurring Behind the Upper Central Incisors. (Salter.)

Pathology in the Arrangement of the Teeth.—A pathological arrangement or irregularity may affect groups of teeth or individual teeth. Among the irregularities which affect groups of teeth are cases in which the anterior teeth of the upper jaw project so far in advance of the corresponding teeth of the under jaw that a considerable space exists between the anterior surface of the lower teeth and the posterior surface of the upper teeth. This arrangement is in many cases hereditary, but may be induced by thumb-sucking in infancy. Infants addicted to this habit place the thumb between the front teeth and pry the upper teeth forward, using the under as a fulcrum. The force exerted is very slight, but, being continued for perhaps several hours during the day, is sufficient to move the imperfectly calcified bony alveolus.

An irregularity the reverse of the above, and of frequent occurrence, is produced when the anterior teeth of

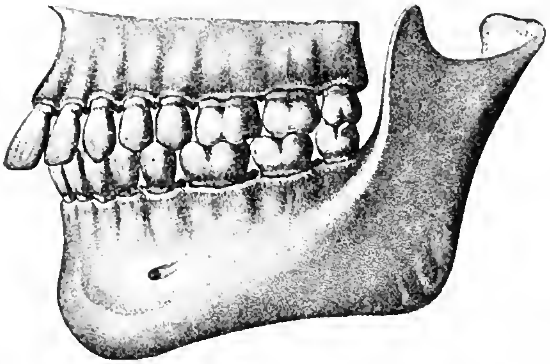

FIG. 4613.—A Case of Projecting Upper Front Teeth. (Carabelli.)

the under jaw are placed in advance of those of the upper jaw, leaving an interval between their posterior surfaces and the anterior surfaces of the superior teeth. To this condition the name underhung jaw has been given.

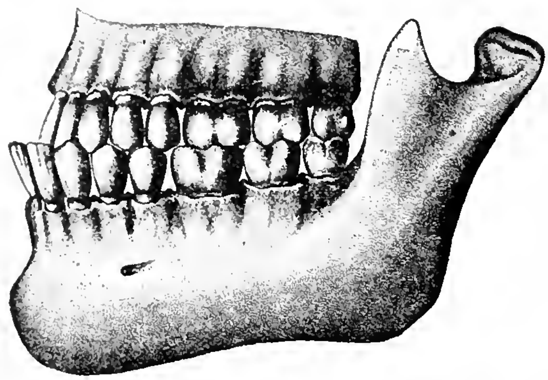

FIG. 4614.—An Underhung Jaw, the Lower Front Teeth in Advance of the Corresponding Upper Ones. (Carabelli.)

It is usually hereditary, and results either from an overdeveloped under jaw or from an underdeveloped upper jaw, the under jaw being normal. This irregularity, as well as the one first described, is very unfavorable to facial expression. The former causes an excessive protrusion of the upper lip beyond the under, and the latter a protrusion of the under lip beyond the upper. A third irregularity is produced when the superior anterior teeth, instead of slightly overlapping the inferior anterior teeth, meet them edge to edge. This arrangement causes no marked facial blemish, but is detrimental to the teeth, which become worn away by edge to edge contact, and thereby shortened.

The six anterior teeth of both jaws are sometimes tilted forward to a marked degree. This irregularity is commonly caused by the loss of molar and bicuspid teeth, which allows the whole force of occlusion to come upon the anterior teeth. This irregularity causes the upper and under lips to protrude.

On the other hand, the six anterior teeth of both jaws may be inverted, and a corresponding falling in of the lips occurs.

A V-shaped jaw is often seen; this irregularity is confined to the upper jaw, whose alveolar arch, instead of being in the form of a parabola, becomes so contracted in front that it resembles in shape the letter V. In such a jaw the room for the tongue is much diminished, and a thick and somewhat indistinct articulation may result.

There are cases in which the back teeth are of undue length and prop the mouth open so wide that the anterior teeth do not meet. Such an arrangement is likely to keep the lips from closing, except as the result of conscious effort.

The dental arch may be asymmetrical. Such a condition may be congenital, or produced by tongue-sucking in infancy. In this habit the tongue is crowded against the alveolus bordering the upper molars and bicuspids, a constant repetition of force in this direction unevenly spreading and thus distorting the dental arch.

The "flat mouth," so called, is produced when the six anterior teeth of both jaws are arranged in nearly a straight line instead of in a curve. When so placed they join the bicuspids at a right angle, or nearly so, and give a characteristic flatness to the expression about the mouth.

These various irregularities are, as a rule, confined to the permanent set. An underhung jaw has, however, been noticed in the temporary set, followed by the same in the permanent.

Irregularities of individual teeth are to be explained by several causes, of which the most important is the occurrence of a small-sized jaw associated with large-sized teeth, a small-sized jaw being inherited from one parent and large teeth from the other.

The premature extraction of the temporary teeth is responsible for many cases of irregularity. The place of each temporary tooth is taken normally by a tooth of the permanent set, and, unless the temporary tooth remains *in situ* till the permanent is ready to be erupted, there is danger that the place which the permanent tooth should occupy will be encroached upon by an adjoining tooth.

The too long retention of the temporary teeth may produce irregularity. In this case the temporary teeth become an obstacle to the descending permanent teeth, and may deflect them from their course, forcing them to appear inside or outside the dental arch; or, as not infrequently happens, keeping them imprisoned within the maxillary bones.

Irregularities of individual teeth of the temporary set are rare. There may be a slight twisting or lapping of the incisors, but no great deformity has been observed. Most important irregularities occur in the permanent set; the superior central incisors may stand inside the dental arch, so that the inferior centrals close in front of them. Their crowns may be rotated either toward the median line or away from it, or may overlap each other. In the lower jaw the central incisors, owing to the frequent crowding of the lower anterior teeth, are often twisted or overlapped. The superior laterals are more frequently

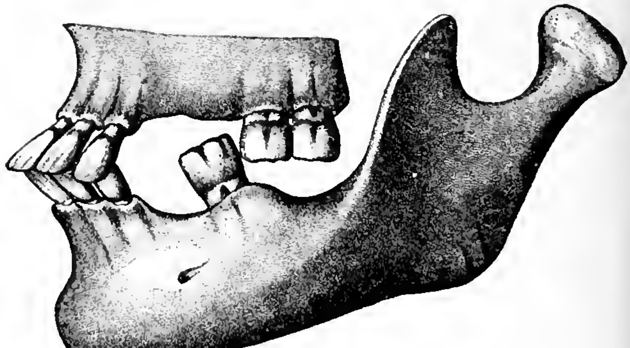

FIG. 4615.—Protrusion of the Anterior Teeth, caused by Loss of Bicuspids and Molars. (Carabelli.)

irregular than are the centrals. The most common irregularity consists in the crown of the lateral overlapping that of the central. The laterals may be placed within the dental arch and held in that position by the interlocking of the lower teeth. Sometimes it happens that they are prevented from eruption by the canines, which have, by premature eruption, occupied their

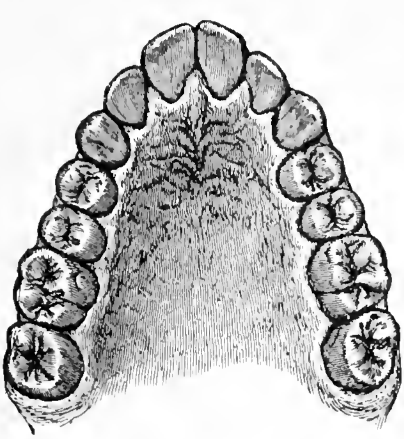

FIG. 4616.—A V-shaped Upper Jaw, from Kingsley's "Oral Deformities." (By permission.)

space. The inferior laterals are liable to irregularities similar to those described in connection with the inferior centrals; such irregularities produce, as a rule, no marked deformity, and are not usually of sufficient importance to be regulated. The superior canines are more often irregular than any other tooth in the mouth. The reason for this is not difficult to find, and has already been partly explained. Erupting, as they do, subsequent to the lateral and first bicuspid, it often happens that the space necessary for their regular appearance in the dental arch has been encroached upon by the adjoining teeth. In consequence the canines must take a position either on the outside of the arch or within. Sometimes the canine takes a position alongside the central incisor; when this is the case, the displaced lateral is usually within the arch. A rotated canine is not uncommon, the rotation being toward the median line or away from it. The lower canines are seldom irregular. The upper first bicuspid also usually finds its normal place, on account of the period of its eruption and the fact that its crown is smaller than that of the first temporary molar which it supplants.

The second upper bicuspid is much more frequently out of place than is the first. Though its crown takes up much less room than that of the second deciduous molar, which it replaces, still the teeth adjoining it (namely, the first bicuspid and first molar), being in position some time before the second bicuspid is ready to erupt, may encroach upon the space which should have been reserved for that tooth. Such a condition usually results from the too early extraction of the second deciduous molar. As a result of such extraction the neighboring teeth move together, and sufficient room is not left for the free eruption of the second bicuspid, and that tooth in consequence, finding its way in the direction of least resistance, is compelled to appear within or without the dental arch, as the case may be. The lower bicuspids are subject to irregularities similar to those of the upper bicuspids, although they occur less frequently. The first and second molars are rarely irregular in either jaw; each in turn being developed behind teeth already in place, there is nothing to crowd them from their normal position. The third molar, on the contrary, has scanty room for eruption, and in consequence presents frequent irregularity. The lower third molar is often found with its crown presenting toward the posterior surface of the crown of the second molar. Sometimes it is tipped forward so far that the force of occlusion and mastication is borne upon its distal surface. This is the most usual form of irregularity, but the tooth may assume almost any position, even with the crown pointing backward toward the ramus of the jaw. The most frequent irregularity of the upper wisdom tooth is the turning of its crown outward or backward.

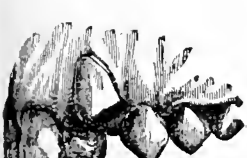

FIG. 4617.—A case in which the superior canine has not room to erupt regularly in the arch, and is forced to appear outside of the arch. (Salter.)

Pathology in Size and Shape of the Teeth.—As a rule, the size of the teeth is in harmony with the proportions of the body. Giants have teeth which would be abnormally large if found in a person of ordinary size. The teeth of males are larger than those of females. When teeth are of unusual size, but proportioned to the size of the individual, they are normal for that individual. There occur cases, however, in which certain teeth are entirely out of proportion to the alveolar arch. Such

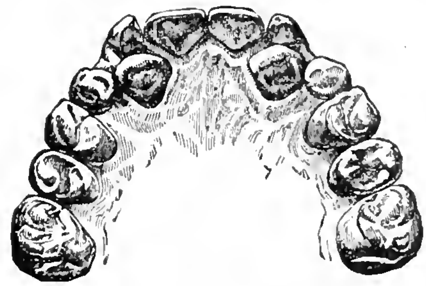

FIG. 4618.—A case in which the superior canines have not room to erupt regularly in the arch, and are forced to appear within the arch. (Salter.)

teeth may be too large or too small. Upper central incisors, in rare instances, become a monstrosity in the excessive size of their crowns; the roots in such cases are not developed in similar proportion.

The superior canines sometimes possess abnormally long roots, whose length may not be suspected till an attempt is made to extract them. Their extraction, on this account, is very difficult, or perhaps impossible. The molar teeth are sometimes abnormally developed, the crowns and roots alike being of unusual size. An abnormal diminution in the size of the teeth is not commonly found, except in the case of the upper wisdom teeth, which are often quite small, no larger than a conical supernumerary tooth. Teeth which are pathological in shape are frequently observed. Their unusual shape may be due to a constitutional disturbance, occurring during their formative period, or it may be due to a freak of nature—a cause unknown. Of the irregular

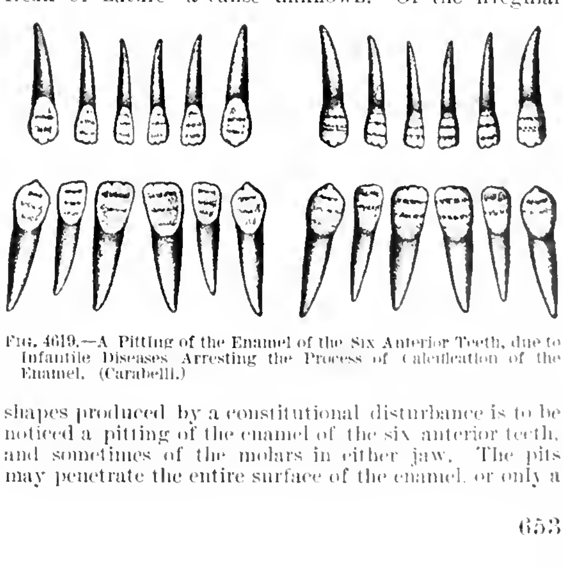

FIG. 4619.—A Pitting of the Enamel of the Six Anterior Teeth, due to Infantile Diseases Arresting the Process of Calcification of the Enamel. (Carabelli.)

shapes produced by a constitutional disturbance is to be noticed a pitting of the enamel of the six anterior teeth, and sometimes of the molars in either jaw. The pits may penetrate the entire surface of the enamel, or only a part of it. They may be irregularly disposed, or, as usually occurs, may be arranged in horizontal rows, of which there may be two or three in a single crown. Sometimes the pits are stained a yellowish or yellowish-

FIGS. 4620 AND 4621 Illustrate the Effects of Hereditary Syphilis on the Superior Incisors of a Boy and a Girl, aged Twelve and Fourteen Years, Respectively. These cases came under the observation of Henry W. Williams, M.D., and are copied by permission, from his "Diagnosis and Treatment of the Diseases of the Eye."

brown color. This irregular development is caused by some severe infantile disease occurring during the period in which the enamel of these teeth is being calcified, the process of calcification being thus interrupted. The administration of mercury in the early years of childhood has also been considered by some to account for this irregularly formed enamel, but such a view is not now generally accepted.

Another malformation due to a constitutional disturbance is that produced by inherited syphilis. The effects of this disease upon the teeth are most notably seen in the upper central incisors of the permanent set. The crowns of these teeth are stunted in size, are somewhat irregularly placed, and their cutting edges are narrower in width than are the necks of the teeth. The enamel on their cutting edges is imperfectly developed and soon crumbles away, leaving crescentic notches. The upper laterals and canines, as well as the lower centrals, laterals, and canines, may be affected in a similar but less marked way. The first molars are usually imperfectly developed, and from a loss of enamel the corners of the teeth are rounded off, giving to the crowns a domelike appearance. As the characteristics of teeth affected by inherited syphilis were first described by Jonathan Hutchinson, it is common to call such teeth Hutchinsonian teeth. They are also called notched teeth, from the notch which may be found in the cutting edge of the six anterior teeth. This notch, however, is obliterated by wear, and thus in time becomes lost as a diagnostic sign. The term peg teeth in this connection is commonly used, and refers to the peglike appearance of the crowns of the anterior teeth. The peg shape does not become obliterated by wear, and always remains a diagnostic sign. While inherited syphilis does not always leave its mark upon the teeth, yet when the appearances described are present they are considered to be positive evidence of this disease. The temporary teeth are said by good authority to be sometimes affected by hereditary syphilis, and to become notched and peg-shaped after the manner of the permanent teeth.

FIG. 4622.—A Case of Fusion of the Superior Central and Lateral Incisors.

Pathological shapes to be ascribed to a freak of nature are not commonly met with; still, a large number of such cases have been reported and drawings made to illustrate them. As one of the more frequent irregularities may be mentioned the fusion of adjacent teeth. There are two kinds of fusion: in one the union is accomplished by the cement of one root becoming increased and uniting itself to the cement of another root. In such cases each tooth has a separate pulp cavity and independent nourishment, the union being merely upon the outside and not affecting the individuality of either tooth. The other kind of fusion consists in the union of the dentine as well as the cement, and a fusion of the pulp cavities into a single irregularly shaped space. Such teeth have a common and interdependent life.

Fusion of this kind may be confined to the roots or include the crown as well, in which case a union occurs between the enamel of the two teeth. Fused teeth may be found in the temporary or in the permanent set, and any teeth may be so affected. Generally the fusion is confined to two teeth. It is sometimes unsuspected when involving only the roots, and the attempt to extract either of the fused teeth may result in its companion also being dislodged, or in a failure to extract either. The first form of fusion probably takes place after the formation of the teeth, the latter while the teeth are in a developmental stage.

There are irregular shapes not due to fusion, and which come under the head of miscellaneous forms. The incisors sometimes have their crown developed at right or obtuse angles with their roots, or have more than one root. The canines may have a twisted root, or one with a sharp bend occurring at the middle or upper end of its length. The bicuspids may have two or even three roots. In consequence of the tendency of the roots of the bicuspids to bifurcate, this occasional development of two distinct roots is to be expected. The upper and lower molars may have as many as five roots, or all their roots may be fused into one.

Pathology of the Component Tissues of the Teeth.—Of these tissues the pulp is most subject to pathological changes. Normally this delicate and sensitive organ is well guarded by rigid walls, which not only protect it against external force, but also against the extreme thermal changes to which the oral cavity is exposed. So long, then, as the pulp remains thus protected, it is not subject to pathological changes; morbid processes do not originate in its tissue. It is true that there are writers who describe affections of the pulp independent of outside influences, but the genuineness of such cases has not been well established. In general the pulp is subject to pathological changes similar to those found in the soft tissue in other parts of the body; such peculiarities as are found are due to the existence of the pulp within a bony incasement. It must be borne in mind that the pulp is very vascular and very sentient; that the vessels and nerves are supported by a parenchyma of connective tissue, and that the whole organ is contained in an unyielding cavity whose only entrance and exit is a small foramen, whose calibre may not be larger than a bristle. Through this foramen the blood enters, and is in due time returned—a delicate piece of machinery capable of easily performing its duties when in natural adjustment, but impaired or destroyed when affected by force from without. Any agency which interferes with the protection which nature has thrown around the pulp is calculated to set up morbid changes in its structure and interfere with its function. The most potent and frequent agency to be named is caries. When once this disease has located itself upon a tooth it usually progresses, unless checked by appropriate mechanical means, till a considerable portion of the enamel and dentine is destroyed and the pulp laid bare. Long, however, before the pulp is reached it has been subjected to conditions unfavorable to its healthy activity, and the chances are that when exposed by caries it is already in a pathological condition.

FIG. 4623.—A Right Superior Canine with an Abrupt Curve at the End of the Root.

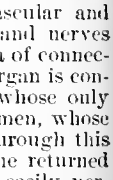

FIG. 4624.—A Superior Bicuspid with Three Roots.

An agency in producing disturbances of the pulp less important than caries is the natural wearing away of the substance of the teeth in the process of mastication. Such wear is usually without serious effect upon the pulp up to the period of middle life. Subsequent to that time, however, it may so deprive the pulp of its natural covering as to induce pathological changes.

A third outside agency, and one less frequently met with than the other two, is mechanical violence, in the form of a blow or fall, of such a nature as to sever the union between the pulp and its blood and nerve supply. Under such circumstances the pulp, as a rule, dies. There are, however, cases reported in which a sound tooth having been pushed out of its socket has been replaced, and the pulp has apparently remained in a healthy condition. Such cases lend support to a supposition that a reunion is possible between the pulp and its blood and nerve supply; but this point has not yet been satisfactorily settled.

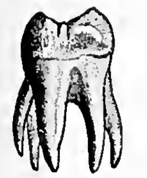

FIG. 4625.—A Molar Tooth with Five Roots.

One of the simplest and commonest pathological affections of the pulp is congestion. A pulp examined in this condition shows increased redness, due to an increased flow of blood to the part and dilatation of the vessels. This condition is brought about through the vaso-motor system, which responds to an irritation of the dentinal fibrils, which are in connection with the nerves of the pulp, and so with the general nervous system. Inasmuch as the normal pulp fills its cavity, an increased supply of blood must compress the tissue in the neighborhood of the vessels. The nerves share this compression, and hence the severe pain which is the usual accompaniment of a congested pulp. Caries of the tooth is the most common cause of congestion of the pulp. Through it a cavity in the direction of the pulp is produced which allows hot and cold drinks, food, and cold air to approach so near the pulp that they irritate it. Salt and sweet substances, also, if allowed to enter the cavity produced by the caries, will act upon the dentinal fibrils and irritate the pulp. A congested pulp is hypersensitive, giving pain upon the slightest occasion. A draught of cold water, the effect of which upon a normal pulp might be but a momentary twinge, would cause a congested pulp to ache violently. This ache is one of the more common kinds of toothache; it is violent, intermittent, throbbing. It is very likely to be worse at night when the body is in a recumbent position. Congestion of the pulp does not necessarily result in a permanent pathological condition, provided the environment of the pulp can be so improved as to become normal, or nearly so. The normal environment may be restored by filling the cavity produced by caries, the pulp being thus removed from the near approach of heat or cold and irritating substances. The filling material should be a poor conductor of heat and cold, resembling in this respect, as far as possible, enamel and dentine. Gutta-percha or oxyphosphate cement have proved the best substances with which to protect a congested pulp. It frequently happens that the pulp becomes congested in a tooth which contains a large metallic filling. The metal filling, being a good conductor of heat and cold, conveys injurious shocks deep into the dentine and unfavorably affects the pulp. Such a condition may be remedied by substituting a non-metallic filling for a metallic one.

FIG. 4626.—A Molar Tooth whose Roots are Fused into One.

While a congested pulp may recover its normal condition, it frequently passes into a state of inflammation which may be either acute or chronic. In acute inflammation there succeeds to the active hyperæmia of congestion a stasis of blood in the inflamed portion; the vessels become dilated more than before, and often assume a tortuous course. The leucocytes can be seen leaving the capillaries and invading the surrounding tissue. If the inflammation is purulent, pus cells and broken-down tissues become abundant. The affection may be local, confined to a small point which has been exposed by caries, or it may be general, involving the entire pulp. The organ is swollen, as in congestion, and pain results from pressure upon the nerve fibres. If the inflammation is very violent, it is likely to destroy the life of the pulp in a short time, through pressure upon the blood-vessels at the foramen. The symptoms attending an inflammation of the pulp are similar to those of a congested pulp, but more severe. The pain is violent, throbbing, paroxysmal, and is commonly known as a "jumping toothache." The tooth is extremely sensitive to heat and cold, to sweet and salt substances, and to pressure within the cavity of decay.

Such an acute inflammation may subside or pass into a chronic inflammation, the symptoms of which resemble those of the acute, but are of a less severe grade. The cause of inflammation of the pulp is caries, which, as a rule, has penetrated to the pulp cavity and laid bare a minute portion of that organ, exposing it to the irritation of foreign bodies, thermal changes, and the secretions of the oral cavity. When suppurative inflammation occurs, the probable agency of bacteria is of interest, as it is well known that many varieties of these organisms exist in the mouth. Their approach to the pulp is made easy through the carious cavity, which lays bare the pulp, and the conditions seem favorable for their peculiar activity. Dr. H. C. Ernst says, in his "Consideration of the Bacteria of Surgical Diseases" (page 4): "The point being determined that there is at least a very strong probability that no suppuration occurs without the presence of bacteria, the study of the organism concerned in these processes becomes at once of great interest." Dr. Black, in the "American System of Dentistry," vol. i., p. 854, says: "I have found suppuration, or more properly ulceration, following a very superficial inflammation, in which the tissue was apparently melting down into a sanious pus thickly inhabited by micro-organisms." The course pursued by an inflammatory affection of the pulp depends largely on the extent to which its surface has been exposed through caries. That there is always such an exposure in case of inflammation of the pulp cannot be affirmed, but that it does exist in the large majority of cases is attested by experience. If this exposure is small and allows no relief to the swollen condition of the organ, and no sufficient outlet to products of inflammation, then an acute inflammation is likely rapidly to destroy the pulp, and transmit an inflammatory process along the root canals to the peridental membrane. If, however, the pulp has been freely exposed before an inflammation has been started up, then the inflamed pulp has a way of relief to its enlarged substance, and an exit for the products of inflammation. Such cases are more likely to assume a chronic form, inasmuch as the life of the pulp is not immediately threatened. It is a matter of some chance, in the case of a pulp exposed by caries, just how soon an inflammatory affection will be started up, though no pulp when once exposed can long escape. If the cavity which exposes the pulp is hidden away in the back of the mouth, or protected by adjoining teeth, so that the pulp of the tooth is, in a measure, protected from alternations of temperature and severe contact with food, then the inflammatory affection may be delayed, and, when it does come, decay may have so opened the pulp cavity as greatly to modify the severity of the inflammation. On the other hand, when caries attacks the crown of the first molar and lays bare the pulp, it is immediately subject to severe irritation in the process of mastication, and trouble begins at once. Inflammatory affections of the pulp do not tend to recovery, but generally end in death of the pulp. This result may be, however, somewhat delayed by appropriate treatment. The exposed pulp may be capped over with non-irritating, non-conducting material and thus shielded. It is sometimes possible to prolong the life of the pulp several years, provided the treatment is not long delayed after the beginning of the inflammatory affection. After having been thus treated the pulp may give no further sensation of pain; it does not, however, often regain its normal condition when it has once passed through the inflammatory process.

To alleviate the pain of a congested or inflamed pulp it is important, first, to determine which tooth is giving trouble. The testimony of patients cannot be relied upon to settle this point. They can usually indicate correctly the side upon which the affected tooth is located, but will often point to a perfectly sound tooth as the cause of their pain. A thorough examination should be made, by the aid of the mouth mirror and a fine exploring point, of all suspected teeth. If a tooth is found with a carious cavity of any considerable size, especially if the cavity is sensitive to the touch of an instrument, it is fair to infer that such a tooth is the one giving pain. The diagnosis can be confirmed by the application of a little cold water to the cavity of decay. Where a congested or inflamed pulp exists, this application will cause an exacerbation of the pain.

Having located the tooth which is the seat of the difficulty, its carious cavity should be washed out with a syringeful of warm water, in order to remove irritating particles of food. The next step is to make an application to the exposed pulp, or, if the pulp is not exposed, to the dentine in the neighborhood of the pulp, which will allay the pain.

A simple and efficacious remedy is the oil of cloves. More powerful remedies are: carbolic acid, ninety five per cent.; creosote; a mixture of equal parts of oil of cloves and chloroform; a mixture of equal parts of oil of cloves and creosote.

One drop of any of these remedies is usually sufficient for a single application. The medicine should be applied to the cavity on a pledget of cotton. Care should be taken not to press the cotton too tightly into the cavity, as it might thus become a mechanical irritant to an exposed pulp. In the use of concentrated carbolic acid, care should be taken to prevent its spreading to the adjoining gum and mucous membrane of the lips and cheek.

It is very important, in treating toothache, to know whether the pulp in the affected tooth is alive or dead. If alive, it will respond to thermal changes and be sensitive to exploration in the carious cavity, and should be treated as just described. If the pulp is dead the tooth is usually sore to percussion, and unaffected by applications of cold, though heat will sometimes be painful.

It is not sensitive to the exploration of an instrument in the cavity of decay. The carious cavity of such a tooth should not be plugged with a dressing, but should be opened freely to give vent to the decomposing pulp in the manner described in the section on affections of the peridental membrane.

Closely allied to inflammation of the pulp is abscess of the pulp. This affection, clinically, cannot always be distinguished from the preceding. Upon microscopic examination, however, it is possible to make out true abscess cavities. These may be deeply situated in the body of the pulp, or near its surface.

Among the more advanced pathological changes in the pulp may be mentioned gangrene. This, as in other parts of the body, may be moist or dry. Gangrene follows upon the sudden cutting off of the circulation from the pulp, as a result of acute inflammations, or violence to the tooth of such a kind as to sever the artery at the apical foramen. A gangrenous pulp is of a grayish-green color, of slight consistence, and fetid odor. In such a pulp the normal structural elements become undistinguishable. In dry gangrene the pulp contracts to a very small compass, and the part of the pulp cavity thus left vacant is occupied by a gas of decomposition. Gangrenous pulps, unless the pulp cavity is freely opened, produce severe inflammation of the peridental membrane.

Another group of pathological changes embraces the various forms of calcification to which the pulp is subject. Among such may be mentioned the nodular form. In this variety small nodules of calcareous matter are sprinkled through the substance of the pulp, giving to it a gritty feel. The calcareous matter is similar in chemical composition to dentine, but does not have its characteristic structure. The calcareous nodules are located between the component parts of the pulp, and are not formed at their expense. This condition seems to be compatible with a healthy activity of the pulp, and apparently does not lead to serious consequences. Its etiology has not been explained. Another form of calcification exists, in which the new formation takes the place of the normal tissue of the pulp and is formed at its expense. The calcareous points are found scattered here and there through the pulp, usually in the coronal portion. These points become confluent till an aggregation is formed ranging in size from a grain of sand up to a mass sufficient to fill the entire pulp cavity, coronal and radical portion as well. This form of calcification apparently does not take place when the tooth is in a normal condition, but seems to be induced either by the wearing down of the crowns of the teeth or by caries. In both cases the dentinal fibrils are subject to irritation, and this irritation determines the deposition of lime salts in the substance of the pulp. When once such a deposition begins, it tends to increase till the pulp is changed from a highly sensitive living organism to one practically lifeless, without nerves or vessels, and without the system of tubules which exists in the dentine. During the course of calcification quite severe pain may arise, evidently due to the pressure of the calcareous masses upon the nerve filaments.

A pathological change similar to that occurring in calcification of the pulp is that which takes place in the formation of secondary dentine. This formation is found on the periphery of the pulp at a place adjacent to a carious cavity, and is deposited by the odontoblastic layer of the pulp, which is the formative agent in normal dentine. Secondary dentine is evidently a means taken by nature for the protection of the pulp against the injurious influences incident to advancing caries. Secondary dentine is similar in structure to normal dentine, containing, like it, tubules and fibrils. Its formation is, however, somewhat less regular, and in case the secondary dentine extends far toward the interior of the pulp, it loses its supply of dentinal tubes and becomes less like dentine and more like a calcified pulp. While the formation of secondary dentine in the neighborhood of decay undoubtedly tends for a time to prolong the life of the pulp, experience seems to show that secondary dentine, when once deposited, tends to increase to such proportions as in the end to destroy the life of the pulp.

The process just described is to be distinguished from that deposition of dentine which takes place by degrees during the whole life of the tooth. This deposit is very slow in formation, and takes place uniformly around the inner side of the whole pulp cavity. By this physiological deposition of dentine the pulp cavities in the teeth of old people are reduced to very small proportions. This seems to indicate that the pulp is useful and necessary inversely to the age of the tooth.

There remains to be mentioned a pathological change which increases the size of the pulp. Such an increase can occur only in case the pulp has been exposed. Let such a pulp be subjected to the irritation of foreign substances, and likewise to that of the sharp edges of a carious cavity, and it will sometimes proliferate and fill the cavity.

Why the pulp does not become inflamed and destroyed under such circumstances cannot be explained. This process has usually been noticed in the case of young teeth. The growth may assume the size of a pea, or be larger. It is of fleshy consistence, and is organically united to the pulp by a narrow pedicle, hence it is called polypus of the pulp. In microscopic examination it is found to consist of numerous round and spindle-shaped cells, interspersed with fibrous tissue, and an epithelial covering has been described by some writers. Its blood-vessels pursue a tortuous and irregular course, unlike those in the pulp. No nerves have been found in this tumor, yet it is slightly sensitive to touch, resembling the gum in this respect. Sometimes a muco-purulent discharge issues from its periphery. A polypus protects the pulp against external violence. It is extremely tenacious of life, and will grow again if cut off.

A growth similar to a polypus takes place in some cases of fractured teeth. The pulp, having been exposed, proliferates through the openings caused by the fracture and forms a tumor outside the pulp cavity. This tumor, morphologically, resembles a true polypus of the pulp; it has, however, a nerve supply, and is quite sensitive to the touch, thus differing from a polypus. Salter has named this growth a "sensitive sprouting of the pulp."

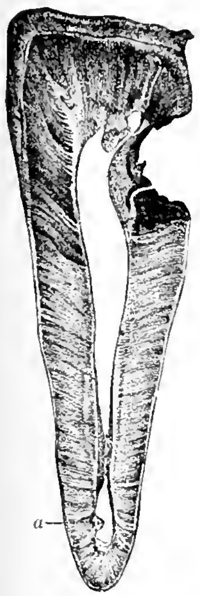

FIG. 4627. — An Incisor Tooth Affected with Caries. a, A deposition of secondary dentine about the cavity of decay.

Under pathology of the dentine the most important process to consider is caries. This process affects the enamel and cementum as well as the dentine, but has more to do with the dentine than with the other tissues. In the first place, it may be said that caries of the teeth does not resemble caries of bone. The term caries as applied to the teeth is a misnomer, given at a time when the true nature of the process was not understood. However, the term has become so generally used that it cannot now be easily dropped. The pathological change which occurs in caries is a decalcification and disintegration of the several tissues of the teeth. The latter condition follows very quickly upon the former, on account of the large proportion of earthy constituents existing in the parts attacked. Caries may affect any of the teeth of either dentition, but it affects certain teeth more frequently than others. Magitot has tabulated ten thousand cases of caries occurring in the permanent teeth, and his tables show that the tooth most liable to caries is the first lower molar, after which follow in succession the first upper molar, the second lower molar, first upper bicuspid, second upper bicuspid, upper lateral, second upper molar, upper central, second lower bicuspid, upper canine, first lower bicuspid, upper wisdom, lower wisdom, lower canine, lower central, and lateral. Caries not only shows a preference for certain teeth rather than for others, but it also shows a preference for certain parts of individual teeth rather than for other parts. Those surfaces of the teeth which are smooth and kept clean by the motions of the tongue, lips, and cheeks, are not attacked by caries; while surfaces presenting an uneven contour, abounding in pits and fissures, are its favorite seat. Hence, we find it located in the crowns of the molars and bicuspids, in the pits on the lingual surfaces of the six superior front teeth, and on all approximal surfaces which, though not uneven, are not cleansed by the motions of the mouth. The buccal and labial surfaces of the teeth, just at the margin of the gum, are likewise often the seat of caries. Caries manifests its presence by a change of color in the tissues attacked. This change may be merely from translucency to opacity, or to a variety of colors ranging from yellow to brown, and even black; sometimes a gray or bluish gray is seen. As a rule, the slower the progress of the disease the deeper the color of the affected parts, and conversely, the more rapid its progress the lighter the color of the affected parts. Caries usually attacks the enamel first, though it may begin with the cementum. It starts in a small pit or fissure, where soon the enamel is found to have lost its peculiarly hard and dense surface. Instead of resisting the most highly tempered steel instruments, as does normal enamel, it crumbles away under slight force. Thus a small opening is made through the enamel to the dentine. This opening may be as large as the head of a pin, or it may be very minute. During this process the enamel has become decalcified and disintegrated. Some authorities say that the centre of the enamel prisms are first affected, and others that the interprismatic substance is first destroyed, in consequence of which the prisms separate and fall to pieces. When once caries has perforated the enamel it no longer confines itself to a narrow area, but spreads out laterally between the enamel and dentine. The degree of lateral extension varies greatly, but seems to be somewhat dependent on the structure of the dentine. If the dentine is well calcified, and with few interglobular spaces, the lateral extension is not so great as when the dentine is imperfectly calcified and abounding in interglobular spaces. The carious process in its lateral extension seems to follow the anastomoses of the dentinal tubules, which are very abundant at the junction of the dentine and enamel. After having affected a certain area on the periphery of the dentine, caries penetrates its substance, following the tubules toward the pulp. Inasmuch as the tubules converge from the periphery of the dentine toward the pulp cavity, the progress of caries is marked by a cone-shaped area, the large end of the cone being in the periphery of the dentine, and the small end pointing toward the pulp. Caries tends to penetrate the pulp cavity, and rarely fails, unless checked by mechanical means. When once the pulp cavity has been penetrated, the pulp is exposed to the degenerative changes already described, and, as a rule, dies and disintegrates. The carious process then invades the pulp cavity, meanwhile spreading laterally through the dentine from the area originally attacked, and disintegrating the enamel from the under side. By degrees the crown of the tooth becomes so hollowed out by the continuous softening and disintegration of the dentine that the shell of enamel left becomes unable to withstand the force of mastication, and consequently is broken away. Nor does caries stop with the destruction of the crown; it continues its work in the root, enlarging the root canal at the expense of the surrounding root substance until the root becomes a mere shell and is finally entirely disintegrated. The carious process in the root is not so rapid as in the crown, and roots may withstand its action for years.

The microscopic examination of the carious process shows the change in color of the affected parts which has been described, and the disintegration of the enamel rods.

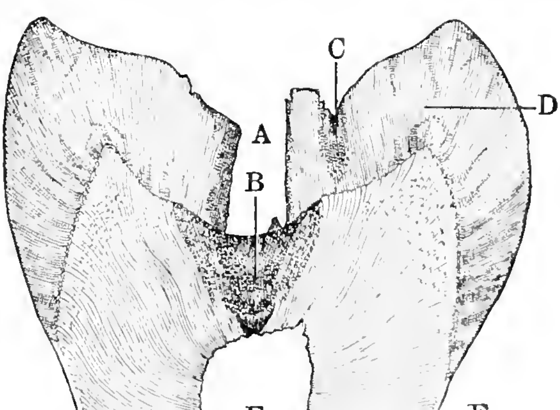

FIG. 4628. —Microscopic Section through a Carious Cavity Occurring in a Molar Tooth. *A*, The initial opening through the enamel; *B*, the cone-shaped area of decay—the affected tissue being discolored and somewhat softened, but not disintegrated; *C*, a minute pit in the enamel where caries has just started; *D*, the enamel; *E*, the dentine; *F*, the pulp cavity.

The tubules of the dentine appear enlarged in calibre; and their size increases as the process advances. The intertubular substance diminishes with the enlargement of the tubules, and finally disappears with the confluence of adjacent tubules. Micro-organisms are found in great numbers within the tubules.

In the cement, the carious process is similar to that found in the dentine. The lacunæ and canaliculi are enlarged at the expense of the surrounding tissue, which softens and breaks down as the process advances.

Micro organisms are present as in carious dentine.

A chemical change to be especially noted in connection with all the tissues affected by caries is the acid reaction which is invariably present.

Etiology of Caries.—There are certain predisposing causes upon which all are agreed; of such may be mentioned a faulty calcification of the enamel, which leaves the dentine exposed; a faulty calcification of the dentine, which leaves it less able to resist degenerative changes; a crowded condition of the teeth, on account of which it is difficult to keep the spaces between the teeth clean.

With regard to the exciting or immediate causes of caries, there has been great diversity of opinion. Of the ancient pathologists, some ascribed caries to a disturbance in the "humors of the body." Others regarded it as due to the ravages of worms which infested the oral cavity.

When we come to observers of scientific repute, we find that the older ones held to a vital or inflammatory theory. According to them, the disease began from within, by an inflammatory process of the dentine or pulp, the process in dentine resembling caries of bone; hence the term caries was applied to it also.

The vital theory of caries has been effectually disproved by the fact that when natural teeth have been mounted upon artificial plates, and thus worn in the mouth, they have been subject to caries, precisely resembling the caries of the teeth normally situated in the jaw.

By others, caries was considered to be a sort of gangrene, due to a disturbance in the nutrition of the dentine.

When, however, the secretions of the mouth came to be studied with reference to their possible agency in producing caries, and when they were found to be at times acid, and when, also, the acid fermentations occurring in the mouth came to be studied in this connection, there was developed what is called the acid theory of caries. According to this theory, caries originates from without and not from within, as those holding the vital theory claimed. The active agency in producing it is acids, which are always present in the mouth, due either to acid secretions or acid fermentations. These acids are to a large extent, it is true, neutralized by the alkalinity of the normal mixed saliva; but in some places, as in the crowns of molars and in the spaces between the teeth, the acid secretions are so protected from the neutralizing influence of the saliva that they are able to retain their reaction and attack the enamel, decomposing the phosphate of lime and other mineral constituents, of which it is largely composed. Having penetrated the enamel, the acids act in a similar manner upon the dentine. According to this theory the tissues of the tooth are affected by chemical decomposition, as if there were no vital element whatever concerned. To substantiate this view many experiments were made, by subjecting extracted teeth to the influence of a weak acid solution imitating conditions found in the mouth. Teeth thus treated underwent a softening and decalcification similar to that found in the mouth in the case of caries. The point was thus well established that caries consisted in the decalcification and disintegration of the mineral constituents of the teeth by an acid.

While some have held a vital theory to account for caries, and others an acid theory, still others again have taken middle ground and held a chemico-vital theory.

The discovery of the presence of micro-organisms in the tubules of dentine affected by caries was an important step in advancing our knowledge of the process. The name of leptothrix buccalis was given to these organisms when first discovered. Though their true agency in caries was not at once understood, they were considered to play an important rôle. Extensive investigations have been made to determine more accurately the nature of the micro-organisms found in the mouth, and their relation to the process of caries. The most valuable of these investigations have been conducted by Dr. W. D. Miller, of Berlin. His method has been to infect sterilized culture media of various kinds with neutral saliva or with neutral carious dentine, and he has found, invariably, that, when the culture medium contains sugar, an acid is produced. By successive cultures he has isolated the organisms which produce the acid. Of the organisms he writes as follows: "We have, then, in carious dentine, two distinct fungi—one always, the other often, present; the former surely, the latter probably, producing lactic acid from sugar" ("American System of Dentistry," vol. i., p. 803). Perfectly sound dentine, subjected to a pure culture of the fungi just mentioned in a medium containing sugar, underwent, in course of time, typical caries. According to Dr. Miller—and his theory is now quite generally accepted—the history of caries is as follows: It starts wherever, from the contour of individual teeth or from the relation of one tooth to another, a collection of food is possible. In every such collection are multitudes of micro-organisms which are capable of thriving in the presence of sugar, and of decomposing this substance and forming lactic acid. This acid decalcifies the enamel and forms a small pit which, being constantly filled with food, offers a favorable nidus for the continued growth of the same organisms. When the enamel has been penetrated, the organisms begin to multiply in the tubules of the dentine, and there continue the decomposition of sugar absorbed from the mouth. The resulting lactic acid enlarges the tubules by the decomposition of the mineral constituents of the dentine. It is possible that at one time the secretions of the mouth may be more unfavorable to the life of micro-organisms than at another, since it is well known that, at certain times and in certain individuals, caries progresses very rapidly.

A condition resembling caries, and yet essentially differing from it, is erosion. Erosion is commonly found on the labial surface of the six anterior teeth, either at the margin of the gum, or between it and the cutting edge. It also sometimes affects the bicuspids and molars. Erosion produces shallow cavities, which involve the enamel and penetrate to the dentine. These cavities are larger at their external opening than in their deeper parts, and are smooth, hard, and polished throughout. They present neither the characteristic softening nor undermining growth which are found in caries. The cavities do not rapidly enlarge, but may become of such size as to threaten the life of the pulp. Caries is sometimes superadded to erosion, thus modifying the course of the destructive process. The etiology of erosion is not definitely determined.

Pathological Changes in the Cement.—The most common pathological change of the cement is an hypertrophy, which is due to an irritation of the peridental membrane. This membrane, lying between the cement of the root and the bony alveolus, is at once the formative membrane of the cement of the tooth and of the adjacent bone of the alveolus. When, however, the cement of the root has been completed, the activity of the peridental membrane, so far as its cement-forming function is concerned, normally ceases. It does not resume this function unless subjected to irritation, in which case it may deposit additional cement upon the root in various ways. The deposit may be diffuse, covering the entire root, though most abundant at the apex. It may be nodular, the nodules being found at any point on the root, and being of various sizes; or it may consist of a club-shaped enlargement at the end of the root.

The added cement is similar in structure to the primary cement, the union between the two deposits being, as a rule, not noticeable. In certain cases, however, blood-vessels penetrate this secondary deposit of cement, a condition not found in the primary deposit. Hypertrophy of the cement has never been observed in the case of the temporary teeth, and affects the permanent teeth during adult life. The teeth most commonly involved are the upper bicuspids and molars, though the others are not exempt. Hypertrophies of the cement are called hypercementoses, osteomata, and exostoses. Of the causes which produce an irritation of the peridental membrane, and consequent hypertrophy of the cement, perhaps the most frequent is caries with its sequelæ, viz., inflammation and death of the pulp, with extension of the inflammation to the peridental membrane. Another cause is the undue pressure which teeth are sometimes subjected to in the process of occlusion and mastication. This arises when many of the teeth have been lost and the few remaining ones are compelled to bear all the strain of service. In such cases the peridental membrane is overworked, literally crowded to the wall, and in consequence may become irritated. The same effect may be produced by the insertion of fillings which project from the crown of a tooth so far as to concentrate the force of occlusion on the filled tooth. While hypertrophy of the cement is commonly due to irritation from undue force, there are cases in which teeth having no antagonists are found to have hypertrophied cement. The symptoms which may arise from an hypertrophy of the cement are caused by the pressure of the new growth upon the nerves of the peridental membrane and upon the nerves of the pulp at the apical foramen. Many cases of hypertrophy exist which occasion no symptoms, the condition becoming known only after extraction. In old people it is usual to find the cement somewhat thickened, and this change can almost be called physiological, so constantly does it occur. Doubtless the process is so gradual that the surrounding tissues accommodate themselves to the enlarged root, and their nerves are subjected to no irritation. In other cases pain is an important and persistent symptom. The pain may be localized and accompanied by a soreness in the socket, or it may be diffused throughout the jaw or reflected to adjoining parts of the head. Severe neuralgias of the head, face, and neck have been found to owe their origin to the hypertrophy of the cement of a tooth. The tooth may appear to be perfectly sound, in which case it is exceedingly difficult to locate the source of the pain. When, however, neuralgias exist in connection with teeth which, though not carious, are the seat of pain or are sore in the socket, it is fair to suspect either an hypertrophy of the cement or a calcification in the pulp. Not only does an enlarged cement cause severe neuralgic pains about the head and face, but cases of epilepsy and insanity have been reported as due to the same cause. A case from Tomes' "Dental Surgery" is in point. "A lad, a farm laborer from Windsor, was admitted into the Middlesex Hospital for epilepsy. The usual remedies were tried for six weeks without effect. His mouth was then examined and the molar teeth of the lower jaw found to be much decayed, the fangs of some alone remaining. Although he did not complain of pain in the teeth or in the jaw, the decayed teeth were removed, and the fangs of each were found to be enlarged and bulbous from exostosis. During the eighteen months that succeeded the removal of the diseased teeth he had not suffered from a single fit, though for many weeks previous to the operation he had had two or three per day."

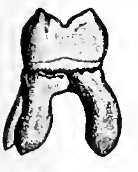

FIG. 4629.—General Hypertrophy of the Cement about the Roots of a Superior Molar Tooth.

A second pathological change of the cement is absorption. This is often found in connection with hypertrophy, and occurs at scattered points and produces depressions in the surface of the cement. In cases of long-continued inflammation about the apex of the root, the cement is likely to be in part absorbed, giving a rough outline to the apex.

Pathology of the Peridental Membrane.—Disease of the peridental membrane may be due to a constitutional disturbance, or to pathological affections of the pulp, or may be dependent upon, or associated with, calcareous deposits upon the root of the tooth. Of the constitutional affections which react upon the peridental membrane, Tomes enumerates rheumatism, syphilis, and the exhibition of mercury.

Inflammation of the peridental membrane from rheumatism is independent of caries, and may involve one or more teeth. The inflammation is distributed over the entire membrane, causing a loosening of the tooth and a soreness in the socket. Its course is subacute or chronic, does not tend to abscess, and is amenable to constitutional treatment.

Inflammation of the peridental membrane from syphilis is chronic. Pus may be discharged around the neck of the tooth, which becomes sore in the socket and loose. If the disease is unchecked the teeth may fall out of their own accord, owing to a complete destruction of the peridental membrane. Associated with this process there often occurs a necrosis of the surrounding bone.

Inflammation from the administration of mercury, whether in the treatment of syphilis or not, is associated with ptyalism, and is of a subacute or chronic character. The teeth become loosened and sore in their sockets, and, if the drug is long continued, a discharge of pus around the neck of the teeth and final loss of the teeth may result.

The effect of phosphorus upon the peridental membrane, though not belonging strictly under constitutional affections, is of great interest. Persons subjected to the fumes of phosphorus, as are those who work in match factories, often have necrosis of the maxillary bones. This necrosis starts with an inflammation of the peridental membrane, which is very sensitive to the irritating fumes of phosphorus. As a result of inflammation the membrane is destroyed, and the bony alveolus being thus cut off in large degree from its source of nourishment, necrosis is invited. It has been found that this disease mainly affects operatives in whose mouth are carious teeth, or who have had teeth extracted while pursuing their occupation. The phosphorus fumes enter a carious cavity and reach the peridental membrane by way of the apical foramen. If, however, the teeth are sound and the gums healthy, phosphorus has little if any destructive effect in the mouth.

Pathological affections of the peridental membrane consequent upon disease of the pulp are of frequent occurrence. When the pulp has become severely inflamed it is common to find, in addition to the symptoms attendant upon simple inflammation of the pulp, a soreness of the tooth in the socket. If the tooth is then percussed with a steel instrument the patient will flinch. This is an indication that the inflammation has proceeded up the root canal and extended to the peridental membrane situated around the apex of the root. Symptoms pointing to inflammation around the root do not always appear during the inflammatory stage of the pulp; they more commonly follow its death and putrefaction. When this has occurred, irritating products of decomposition, both gaseous and liquid, pass up through the canal and set up acute inflammation in the membrane at the apex of the root. In the light of our knowledge of the agency of micro-organisms in inflammatory processes, we must consider that the germs, which were active in producing inflammation of the pulp, are also active in the consequent inflammation of the peridental membrane. This membrane being of connective tissue, and richly supplied with blood vessels, is an excellent field for inflammatory action, and being closely confined between unyielding walls, and having an abundant nerve supply, is capable of producing symptoms of the severest character. When an inflammatory process has started at the apex of the root, the tissues become swelled and engorged with blood, the condition extending from the apex toward the neck of the tooth. In consequence of the swelling of the membrane, the tooth is pushed slightly from its socket and becomes loose. The clinical symptoms are ushered in by a dull, continuous pain, which is not occasioned by changes of temperature, as is often the case with inflammation of the pulp. The tooth upon pressure feels sore in the socket, yet during the first stages of the inflammation a grinding of the affected tooth against its antagonists gives some relief. The inflammatory process sometimes stops at this point, but very often goes on to the formation of an alveolar abscess.

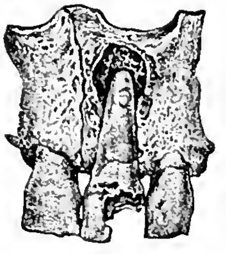

FIG. 4630. — Absorption of Bone, produced by an Alveolar Abscess at the Tip of the Root of a Left Superior Incisor.

Alveolar abscess forms about the tip of the root. As pus collects, the neighboring bony tissue is absorbed, and a cavity is formed varying in size according to the severity of the inflammation. Like abscesses in other parts of the body, it seeks an outlet at the point of least resistance. There are several ways in which the pus may make its escape. It may penetrate the bony alveolus in a line which is, roughly speaking, at a right angle to the root of the affected tooth, and thus make its escape into the mouth, or, in some cases, upon the face. Or it may pass down the length of the root, either between the peridental membrane and the cement, or between the peridental membrane and the bony socket, in both cases discharging about the neck of the tooth. When an alveolar abscess occurs in connection with the six anterior teeth and bicuspids of the upper jaw, it usually discharges on the labial surface of the alveolus, at a point about opposite the tip of the root of the affected tooth. In rare instances an abscess connected with these teeth may discharge on the outside of the front part of the face or into the nasal cavity, and in the case of the bicuspids, into the antrum Highmorii. An abscess occurring in connection with the upper molars most commonly discharges on the buccal surface of the alveolus, about opposite the tips of the roots affected. It may, however, discharge in the neighborhood of the hard palate, when proceeding from the palatal root. Besides these usual points of discharge, the abscess may open into the antrum or upon the outside of the face, near the union of the malar and superior maxillary bone. Abscesses formed about the lower anterior teeth usually open on the labial side of the alveolus, within the mouth. They may, however, open on the outside of the face, below the horizontal portion of the jaw. Abscesses in connection with the lower bicuspids usually open on the buccal side of the alveolus, though they may discharge on the face, along the body of the jaw. Abscesses connected with the lower molar teeth usually find exit upon the buccal side of the alveolus, but sometimes on the outside of the face, adjoining the inferior maxillary bone. Cases are reported in which the abscess has opened in the neck, and even as low down as the infraclavicular region. Alveolar abscesses usually assume a chronic condition, and keep up a discharge of pus from their fistulous opening as long as the root in connection with which they have been formed remains in the mouth, or until the pulp canal of the root has been properly cleaned and filled. The opening of an alveolar abscess upon the face or neck has oftentimes been mistaken for the discharge from necrosed bone. A case coming under the observation of the writer, while in charge of the Dental Infirmary of the Harvard Dental School, will illustrate the point. A farmer, from the western part of Massachusetts, came to the Massachusetts General Hospital to be treated for a fistula opening at the symphysis of the lower jaw. The fistula discharged more or less, and was thought to be due to necrosis of the lower jaw. The condition had existed for about two years, and had been treated by injecting the fistula with various medicaments. At the hospital they declined to operate till his teeth had been examined. Such an examination showed a lower incisor which, though not carious, was believed to contain a dead pulp and to be the origin of the fistula. The tooth was extracted at the Dental Infirmary, and the patient advised to return home and report in a month's time. In due time the patient reported that the fistula had completely healed. While not all cases of fistula about the face are due to dental abscess, yet the teeth should always be examined when such a case presents itself.

The clinical symptoms attendant upon alveolar abscess are well marked and of peculiar severity. Since alveolar abscess starts with simple inflammation of the peridental membrane, the first symptoms are the same as those described under that affection. As the condition advances, however, the pain becomes more intense, the tooth is farther protruded from its socket, and is exquisitely sensitive, the touch of a finger often being sufficient to produce great agony. Sometimes the formation of pus is marked by a chill and rise of temperature. This formative stage may last from twenty-four to forty-eight hours; meanwhile the pus has been working its way through the surrounding bone into the soft parts. When this has occurred the face in the neighborhood of the affected tooth becomes swollen, and there is a marked remission of pain. The mucous membrane of the gum about an alveolar abscess is much congested and swollen, besides being sore to the touch.

As peridental inflammation and alveolar abscess are very common causes of toothache, it is necessary to distinguish between the toothache so caused and that due to irritation of the pulp. Toothache from irritation of the pulp is started by the pressure of food against the pulp, by a sudden variation of temperature, or by sweet or salty substances. The pain is violent, but intermittent, and no soreness of the tooth in the socket, as a rule, exists. Toothache from inflammation of the peridental membrane or alveolar abscess is started by the death and decomposition of the pulp. The pain is continuous; it is increased by the application of heat, diminished by the application of cold. The tooth is sore in the socket, and if the crown is tapped with an instrument the patient will flinch. The tooth is protruded from the socket, the gums are inflamed, and the face is swollen.

The treatment of peridental inflammation or alveolar abscess is, first, to remove the cause of the irritation. If the tooth is without value to the individual it should be extracted. This is the quickest way out of the difficulty. If, however, it is desirable to preserve the tooth, its pulp cavity should be at once opened and cleansed from all decomposing material. If this is done in the first stage of the difficulty it is usually sufficient, and, the source of irritation being removed, the inflammation subsides. If the case be one of alveolar abscess the cleansing of the pulp cavity is of advantage, not only in removing the source of irritation, but also in giving a vent to the forming abscess through the root canal. In many cases, however, the abscess will open through the alveolus in spite of treatment. Such an opening can sometimes be hastened by incising with the lance over the affected root. Whether pus can be reached with the lance or not, the incising of the gum gives relief by diminishing the congestion of the part. The use of leeches upon the gum is an old and often effective remedy. The tincture of iodine painted upon the gum is of

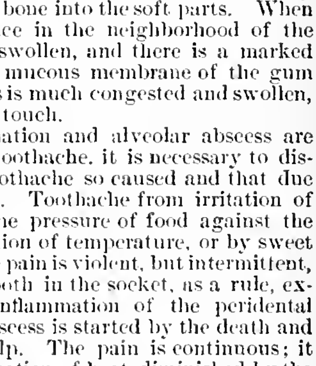

FIG. 4631. A Vertical Section through a Lower Incisor and Surrounding Parts, Illustrating two Ways in which an Alveolar Abscess may find Vent. The first, and more common way, is by the fistula opening at *c*; the second, and less common way, is by the fistula opening at *c'*. *a*, the tongue; *b*, the lower lip; *d*, the abscess cavity; *e*, the inferior maxillary bone.

common use; also the application of capsicum plasters, slippery-elm poultices, and roasted raisins. A poultice should never be applied to the outside of the face, on account of the danger of causing the abscess to discharge externally and leave a scar upon the face which is a permanent disfiguration.

Pathological Affections of the Peridental Membrane dependent upon, or associated with, Calcareous Deposits on the Teeth.—Calcareous deposits are of two classes: those originating from the saliva, and called salivary tartar or salivary calculus, and those originating apparently from a serous exudation from the peridental membrane, and called serumal calculus. The salivary tartar or calculus is composed mainly of phosphate of calcium, which is contained in the saliva and is precipitated upon the teeth. It is found in greatest abundance on the buccal sides of the upper first molars, near the opening of the parotid gland, and on the lingual side of the lower anterior teeth, near the opening of the submaxillary and sublingual glands. Salivary calculus is first deposited at the neck of a tooth, and, if not removed, spreads both toward the cutting edge and in the opposite direction up the root. In its progress along the root it presses away the gum from the neck of the tooth and separates the peridental membrane from its attachment to the cement. If allowed to rest in contact with the peridental membrane, it destroys its life, and also that of the adjacent bony alveolus, thus largely diminishing the natural support of the tooth. In this way the teeth affected become loosened, and may be entirely dislodged. Salivary calculus, though, as a rule, limited to the regions described, may in much neglected mouths cover the entire lingual side of the lower teeth and the buccal sides of the upper teeth. The treatment of this deposit consists in its removal, after which the peridental membrane quickly resumes its normal character, except such portions as have been destroyed, and the gum closes around the neck of the tooth.

The second form of calcareous deposit, called the serumal, has nothing to do with the saliva, nor is it limited to certain localities in the mouth. It is supposed to be due to a deposition from serum exuded from the gingival margin of the gum and peridental membrane; this deposition taking place in consequence of irritation. It may affect any of the teeth, and is located at the margin of the gum, often hidden from sight. In color it varies from yellow to brown, and even black. It often encircles the root of the tooth, but may be deposited in patches. It increases slowly, but is destructive to the peridental membrane, which becomes separated from the root. The alveolar bony processes about the neck of the tooth are in time absorbed, and the natural support of the tooth is diminished.

In connection with this deposit there may be a flow of pus, due to irritation of the peridental membrane. To this condition the name pyorrhœa alveolaris has been given. While salivary calculus causes the loosening and falling out of the lower front teeth, the serumal deposit may effect the loosening and falling out of any of the teeth, and is the most common cause of that result.

There remains to be described an affection of the peridental membrane which is very destructive to that tissue. It is usually associated with a deposit of serumal calculus, and may be very similar to the affection just described. The calcareous deposits are, however, more likely to be in patches, and to advance more rapidly to the apex of the root. By this means pockets are formed along the side of the root, due to a separation of the peridental membrane from the cement of the root. In the first form of serumal deposit the peridental membrane is separated from the tooth around the entire circumference of the root, and from its neck as far up as the deposit reaches; the tips of the root meanwhile being firmly attached to the peridental membrane until the tooth falls out. In the second form, however, the root may be separated from its peridental membrane on one side up to its apex, and in other parts firmly attached. At the apex the root is often entirely separated from its surrounding membrane, though at its neck there may be a fairly good union. Whether the deposit of calculus is due to the inflammation of the peridental membrane, or the inflammation is due to the deposit of calculus, is not decided. This form of calculus is associated with a flow of pus and rapid destruction of the peridental membrane. This membrane having been destroyed, the tooth loses its hold in the socket, and in time drops out. There is some reason to suppose that this disease is due to a special micro-organism, and that it is infectious. On this account it has been called infectious pericementitis. The term pyorrhœa alveolaris is commonly applied to this as to the preceding condition. The treatment of both kinds of serumal calculus with associated inflammation of the peridental membrane is to remove the deposits of calculus and to keep them removed. To this must be added thorough cleanliness of the teeth, and a washing out of all pockets produced by the separation of the root from its membrane. The use of antiseptic and astringent fluids in such pockets is a desirable and effective treatment, especially in that form of deposit last described. In people of middle or advanced life calcareous deposits are more destructive to the teeth than is caries.

Extraction of the Teeth.—The extraction of the teeth may be called for by various conditions, of which the more common are:

1. A crowded condition of the teeth which threatens or has caused irregularity. Teeth may be placed entirely outside or inside of the dental arch. The extraction of such teeth is often advisable. It may, however, be laid down, as a rule, that the superior canines and central incisors should not be extracted to correct irregularity; nor should the inferior canines, except in rare instances. For example, it often happens that when the superior canines make their appearances through the gum there is no room for them between the superior lateral incisors and first bicuspids. As the canines descend they in consequence take a position outside of the arch and are a deformity. They are not on this account, however, to be removed, because by their position and size they give character to the expression of the face. A bicuspid, or sometimes a first molar, should be extracted instead, and thus room gained for the canine. In many such cases, however, there is no need for extraction, inasmuch as the enlargement of the dental arch, either by nature or by mechanical appliances, will furnish the required room.

2. The existence of a few teeth in the mouth which interfere with the adjustment of an artificial plate. This is a very common cause for extraction, inasmuch as a more satisfactory plate can, as a rule, be made for a mouth having no teeth than for one having a few scattered teeth.

3. The existence of pain due to:

(*a*) Congestion or inflammation of the tooth pulp.

(*b*) Inflammation of the peridental membrane.

(*c*) Alevolar abscess.

More teeth are extracted to relieve pain than for any other cause. Where teeth, however, by treatment can be relieved of pain and made useful organs, they should not be extracted.

4. The existence of diseased conditions of the tissues in the neighborhood of the teeth.

An inflammation of the antrum is sometimes best treated by extracting an upper first molar or second bicuspid and making an opening through the end of the root socket into the antrum. By this process the antrum can be thoroughly cleansed and good drainage established. There are tumors of the jaw, and cases of caries or necrosis of the maxillary bones, which necessitate a removal of teeth.

5. The persistence of the temporary teeth when the permanent teeth are about to erupt.

It may be laid down, as a rule, that the temporary teeth should not be removed until the permanent teeth are ready to take their place. When this condition exists, the roots of the temporary teeth have been for the most part absorbed, and the crowns have become loose. While the above rule should be adhered to as far as possible, yet there are cases in which severe inflammation connected with the temporary teeth requires their premature extraction.

The Process of Extraction.—The process may be divided into three stages.

1. Seizing the tooth with the forceps.
2. Loosening its connection with its surroundings.
3. Removing the tooth from its socket.

The process of extraction and the instruments employed vary greatly with the different teeth in the mouth. A knowledge of the number, shape, and size of the roots of the teeth is necessary to insure success in their removal. To extract the teeth of the upper jaw, the patient should be placed with the head thrown well back, and the operator should stand at the patient's right side. With the left hand the lips and cheeks should be retracted and the upper jaw firmly grasped.

The upper central incisors are extracted with a forceps whose beaks are made to adapt themselves to the nearly conical neck of this tooth. The forceps should be applied with one beak at the labial surface of the neck of the tooth, and the other at the lingual surface. The beak of the forceps should be carried well up between the margin of the gum and the root of the tooth. When the tooth has been thus grasped, it should be gently but firmly rotated, in order to loosen it from its socket. A forward-and-back motion may with advantage be combined with the rotatory motion. When the tooth is felt to have been loosened, it should be removed by a steady pull in the direction of its long axis.

The superior lateral incisors are extracted in a manner similar to that of the central incisors, and with the same forceps. Inasmuch as their roots are somewhat compressed laterally, the rotary motion is not so important as with the central incisors.

The superior canines are quite difficult to extract, owing to their very long roots. The upper incisor forceps are usually employed for the canines. The tooth should be grasped as high up on the root as possible. To loosen the tooth from its socket the rotary motion must be combined with the forward-and-back motion. When loose, a straight pull in the line of its long axis is necessary for its removal. It must be borne in mind that the root of the canine is decidedly flattened on its sides, and therefore offers considerable resistance to rotation.

The upper bicuspids may be extracted with the upper incisor forceps; or they may be conveniently extracted with the alveolar bayonet-shaped forceps. The upper bicuspids should be grasped well up on the root and loosened by a side-to-side motion. Their roots being long and slender, great care is required to prevent their fracture. If the first upper bicuspid has a bifurcated root, it is often impossible to remove the tooth without breaking off the tip of one of the roots.

The first and second upper molars are extracted by a forceps whose inner beak is fashioned with a single concavity, it is thus fitted to embrace the inner buccal root of the first or second upper molar. The outer beak is divided by a longitudinal ridge into two concavities, while the tip of the beak is pointed in the middle. It is so made in order to embrace the two buccal roots of the first and second upper molars, and to conform to the depression between these roots. These forceps should be grasped in the palm of the hand, the thumb being brought into position between the angle formed by the two handles and the joint. The third and fourth fingers should be closed over the curve of the left handle. Owing to the divergence of the three roots of the upper first and second molars, considerable loosening is necessary before they can be extracted. This is effected by a side-to-side motion; as the outer alveolar plate is thinner than the inner, the main force should be applied in an outward direction. When the tooth is thoroughly loose in its socket, it can be removed by a downward and outward motion

Upper wisdom teeth are not usually difficult to extract, as their roots are commonly fused together. In order to loosen them they should be turned firmly outward. By this movement their attachment to the socket can be readily broken up and the tooth removed.

In case the crowns of the upper teeth are badly decayed or entirely lost, the alveolar or root forceps should be used. With this instrument any root of the upper jaw can be extracted; the rules for the extraction of roots being substantially the same as those for teeth with crowns. It is necessary, however, to carry the blades farther up into the alveolus than when the crown is present. Great care should be taken not to crush the root by too firm a grasp. With the first and second upper molars it often happens that the three roots must be extracted separately.

In extracting the inferior teeth the patient should be situated much lower down than for extracting the superior teeth. The operator should stand at the patient's right side, oftentimes well to the back. The lower jaw should be grasped by the left hand, and supported from beneath by the palm and last three fingers, while the thumb and forefinger are placed within the mouth to retract the lips and tongue from the tooth to be operated on. The lower incisors, owing to the lateral compression of their roots, cannot be rotated in the process of loosening them. This must be accomplished by a forward-and-back movement.

The lower canines, owing to their very long roots, are often quite difficult to extract. They are to be loosened by a forward-and-back movement, to which a slight rotary motion may be added. When loose, they are removed by being pulled straight up from the socket.

The lower bicuspids should be grasped well down upon the root and loosened by an in-and-out motion. The alveolar plate being much thinner on the outer than on the inner side, it will yield more readily outward. When loosened, the lower bicuspids are removed by being pulled straight up from the socket.

The lower molars are extracted by a forceps whose beaks are divided by a median ridge, and are terminated by a pointed tip; it is thus able to embrace the two roots of the lower molars, and to engage the depression between them. To extract the lower first and second molar teeth, they should be rocked from within outward till loose, using more force when turning them outward than in the opposite direction. When loose, they may be removed by an upward-and-outward pull. The lower third molar often gives great difficulty in extraction, owing to the curve of its roots, which hook backward toward the ramus of the jaw. It must be loosened by a side-to-side rocking. Owing to the backward curve of its roots it cannot be lifted from its socket by a force exerted directly upward.

Elevators are often useful; they are straight and curved levers, with which a tooth is pried out of its socket, a neighboring tooth being used as a fulcrum.

The extraction of the temporary teeth is performed after the same manner as that of the permanent teeth. The operation is, however, much simpler, especially if performed at a time when the teeth are about to be shed by nature. In the premature extraction of the temporary molars there is always the possibility of bringing away the crown of the developing bicuspid, which is located between the roots of the molar tooth. Diminutive forceps are made for the temporary teeth, but temporary teeth can be readily extracted by the root forceps made for the permanent teeth.

Accidents of Extraction.—In the extraction of the teeth certain accidents may occur; they may be unavoidable or due to unskilfulness or carelessness. The following are the more common:

Fracture of the Tooth.—This often happens, and is due usually to an excess of force, or to misdirected force, or to an insufficient grip upon the tooth. Cases occur, however, in which fracture of the tooth is unavoidable; this is especially the case when the roots are misshapen and locked into the jawbone. When the tips of roots are, as the result of fracture, left in the maxillary bones, it is not always wise to remove them. Nature will usually expel them in due time.

Fracture of the Alveolus.—This occurs, to a limited extent, in every tooth extraction, and produces, as a rule, no troublesome symptoms. By unskilfulness, however, a large portion of the alveolus surrounding a tooth may be crushed or fractured, and necrosis sometimes ensues.

Fracture of the jaw may result from tooth extraction. The fracture may be in the upper jaw, or in the body of the lower jaw. It may or may not imply fault on the part of the operator.

Dislocation of the Lower Jaw.—This usually happens with people whose jaws are loosely hung, and are in the habit of slipping out of the socket. If this tendency is known to exist, it is well to apply a roller bandage over the head and under the jaw before operating.

Removal of the Wrong Tooth.—This accident happens, as a rule, only to inexperienced or careless operators.

Removal of Two or More Teeth Instead of One.—This may happen from an hypertrophy of the cement uniting adjoining roots below the gum. It may happen when the tooth to be extracted is overlapped by an adjoining tooth. It may happen also by the slipping of an extracting instrument, whereby a loose tooth is knocked out.

Laceration of the Mucous Membrane of the Gum.—This occurs to a limited extent in every extraction, but, through carelessness or unskilfulness, may be very extensive.

Falling of the Tooth into the Œsophagus or Air Passages.—A tooth will sometimes escape from the grasp of the forceps and be swallowed. From this accident no serious results are to be expected. Cases are now and then reported in which a tooth falls into the larynx. This constitutes the most serious accident that can attend extraction. Such a tooth may be coughed up from the larynx, or it may enter the bronchial tubes, causing symptoms which are always serious and often fatal.

The inferior dental nerve has been crushed in the extraction of the lower wisdom teeth. In such cases a loss of sensation has occurred in the lower part of the face. Usually this passes away, though it may be permanent. In attempting to extract the roots of the upper bicuspids and molars they have been pushed into the antrum. When this happens, the opening into the antrum should be enlarged and the roots removed.

Hemorrhage after Extraction.—This is usually moderate in amount and of short duration. Such cases require no treatment. There are cases, however, in which the hemorrhage is so prolonged as to produce alarming symptoms, and in rare instances death has resulted. Great care should be taken in dealing with people having the hemorrhagic diathesis. To control hemorrhage after extraction the most successful method is to apply pressure to the bleeding parts. The bleeding usually takes place from the socket of the extracted tooth. The socket should be packed with cotton, lint, sponge, or any soft unirritating material. After packing the socket a compress of soft material, covering the socket and surrounding parts, should be superadded. Upon this compress a gentle pressure should be maintained, either by the fingers or by the opposing jaw. An effective method of applying pressure after the socket has once been plugged is to soften a piece of gutta-percha in hot water and mould it to the affected region. Enough gutta-percha should be used so that the opposing teeth or alveolus can be embedded in it by the closing of the jaws. Let the jaws be closed and a roller bandage passed over the head and under the chin, and firm and constant pressure is secured upon the bleeding area.

In severe cases care should be taken to keep the head upright and the extremities artificially warmed.

As styptics can be mentioned perchloride of iron, tannic acid, and preparations of the suprarenal capsule. Of these, perchloride of iron is the least valuable. Tannic acid is a reliable agent; the powder may be applied to the socket on a pledget of cotton. Preparations of the suprarenal capsule are especially valuable in arresting dental hemorrhage. Styptics can be used with advantage in connection with the use of pressure, as described above. Very severe cases of hemorrhage have been controlled by the use of the actual cautery. If this be used, it should not touch the parts, but be held just near enough to bake them. If the cautery touches the tissues, a fresh laceration is made by its removal.

In desperate cases of hemorrhage internal remedies are usually resorted to. They consist of tannic acid, gallic acid, and ergot.

General Considerations.—Haste in extracting should be avoided; the hand should never move faster than the eye can follow. The tooth should be under complete observation from the time it is grasped by the forceps till it is out of the mouth. The head of the patient should be firmly fixed, and under the control of the left hand or arm.

While considerable force is necessary to extract a tooth, the force should be so guarded and moderated as not to endanger surrounding parts. No jerks or sudden pulls are allowable.

The forceps should never grasp the crowns of teeth alone, as the crown will usually break off, leaving the root undisturbed, but should engage the tooth at its neck, or a little higher up if possible.

In extracting roots the beaks of the forceps should follow down between the root and its alveolus till a firm hold is obtained.

The cutting through of gum and alveolus with a root forceps is not a desirable procedure, but is allowable in certain cases.

An excellent substitute for a dental chair is a rocking-chair with medium high back, a pillow thrown over the back forming a good head-rest.

William Henry Potter.

TELANGIECTASIS; TELANGIOMA. See *Angioma.*

TELLURATES.—The tellurate of potassium and the tellurate of sodium are recommended as remedies for the profuse sweatings due to phthisis and other causes. They are given in doses of one-third to one-half grain daily. In some cases this quantity requires to be increased, but generally the second or third dose is followed by a cessation of the sweating. It is supposed to produce its effect by an inhibitory action on the nerves of the sweat glands. In some cases it causes a loss of appetite and nausea, and in some advanced cases the sodium salt has produced a profuse liquid diarrhœa which is very difficult to check. The most serious obstacle to its general use is the persistent garlicky smell which it communicates to the breath and to the perspiration.

Beaumont Small.

TENDON REFLEX. See *Knee-jerk*, and *Reflexes, Clinical.*

TENDONS AND THEIR SHEATHS, INJURIES AND DISEASES OF.—It is most unusual to find tendons diseased independently. Morbid conditions of the tendons are so commonly the result of disease in their sheaths that in most systematic treatises they are not separately described. Owing to their dense fibrous structure and an intrinsic blood supply that is far from abundant, they lend themselves more easily to disturbances of nutrition than to invasion by infectious processes. Arcoleo has shown experimentally (*Gaz. degli ospedali*, 1898, No. 151) that the intactness of the sheath is necessary for the perfect nutrition of the contained tendon; but, on the other hand, that the complete removal of the sheath is not followed by necrosis of the tendon.

The most frequently observed morbid conditions of tendons themselves have been in cases of the so-called "snapping finger" (*schnellender Finger, doigt à ressort*). This consists of a sudden interference with the movements of extension and flexion, or of either alone. It occurs always at the same period of the movement, and is overcome with a peculiar snap, either as a result of great muscular exertion or with the assistance of the other hand. In some instances its nature has remained obscure, but operations for its relief have disclosed a nodular thickening of the tendon in quite a number of instances. It is, under these circumstances, probably most often of traumatic origin, but has on rare occasions been ascribed to tuberculosis, syphilis, and neoplasms. Operative removal has been almost invariably successful in its treatment; this may at times be accomplished without completely severing the tendon.

With this exception, disease of tendons will almost invariably be found coincident with or consecutive to primary disease of the sheaths. Malignant growths, tuberculosis of articular origin, and acute suppurative processes frequently involve the tendon sheaths in their extension. These do not require separate description in this place.

In consequence of overexertion or traumatism, there is sometimes observed in the extensor tendons of the hand (less often in the leg) an acute, dry inflammation of the sheaths, *tenosynovitis acuta sicca*. It is apt to occur in persons whose occupations necessitate excessive use of a particular muscle or group of muscles, and especially if there is superadded to the accustomed amount a period of forced labor carried beyond the point of fatigue. The disease has been observed with a certain frequency in washerwomen, pianists, fencers, carpenters, and gymnasts, being in them localized at the wrist. At the ankle it occurs frequently in porters, and infantrymen, and still more often in women operating sewing machines. The prolonged use of the hand trephine has occasionally accounted for its appearance in the surgeon's wrist. A fibrinous exudate upon the surface of the tendon and its sheath gives rise to a rubbing or creaking sensation to the examining hand, whence the name "tenalgia crepitans." It has in some instances also been considered as the result of gonorrhœa or syphilis. Under these conditions, but also in their absence, a serous effusion may appear. When it does so, the crepitation is masked by it to an extent proportionate to the amount of fluid which has been poured into the sheath. Considerable pain and disability may be associated with it. It may be made to subside promptly by fixation of the part by splints, or, still better, by a plaster-of-Paris dressing, this to be followed in from ten to fourteen days by a course of massage and superheated air.

Acute suppuration of the tendon sheaths occurs most frequently in consequence of infected wounds, but may result by extension from phlegmonous processes without demonstrable traumatic origin. It is of especial frequency in connection with wounds of the fingers, when it is spoken of as thecal whitlow. We have here to deal with a most painful septic condition; redness, swelling, intense pain, and throbbing are present. The constitutional symptoms are, or may rapidly become, alarming, and unless incision of ample length is promptly made the tendon will be completely lost by slough; this being escaped, adhesion between the tendon and its sheath occurs, so that its function may be completely abrogated. Prompt and free incision with thorough drainage and preferably moist antiseptic dressing (1 to 5,000 sublimate), to be followed by elevation of the affected part, may be depended upon to avert these unfortunate terminations in the greater number of cases. For this reason such temporizing measures as poulticing, the application of cold, and incisions of very limited extent are to be avoided.

Chronic simple inflammation of the tendon sheaths may be considered as occurring very infrequently. To such an extent is this true that all chronic disease of tendon sheaths is ascribed by some writers to tuberculosis. It has been shown, however, that this is not justifiable, but that *chronic simple tenosynovitis* may occur as a dry, serous, or hemorrhagic inflammation. The dry form is characterized, like its congener of the acute variety, by crepitation upon movement of the tendon in its sheath. Gout and continuous overexertion have been held responsible for it. The serous variety has doubtless been looked upon as tuberculous by many, but is sometimes the result of trauma, rheumatism, or gonorrhœa. Blake has reported a case (*Annals of Surg.*, xxxiv., p. 577) in which operation and subsequent careful microscopic examination showed its non-tuberculous character beyond question. According to Lejars, it is most frequently due to repeated traumatisms, and must sometimes be regarded as a disease of occupation. It presents itself as a fluctuating swelling in the course of the affected tendon, the movement of which is usually interfered with or is productive of discomfort. It is frequently difficult to distinguish it from tuberculous hygroma (see below) without exploratory incision. Aseptic incision is, however, the treatment most likely to be successful. The hemorrhagic variety has, in the few reported cases, been the sequel of trauma. Juvara has reported three cases of such effusion into the sheaths of the radial extensors (*Rev. de Chir.*, June 10th, 1902). There was present an almond-shaped, fluctuating tumor which could be made to slip about by pressure. There was no crepitus to be obtained.

Tuberculosis of the tendon sheaths is by all means the most frequent of the chronic conditions affecting these structures. It is, however, less often primary than secondary. In this latter case it usually occurs by extension from a bone- or joint-focus. This is frequently observed at the wrist and ankle. As a primary condition it is, however, far from rare, and is frequently found in individuals showing no other predisposition to tuberculous infection. For this reason, and because its course may be extremely chronic and unaccompanied by great disability, its real nature is often not appreciated, and is considered rheumatic.

Three forms are usually described, but should not be considered as pathologically distinct, as they are frequently found in combination. The first form may be described as the *tuberculous hygroma*. This presents itself clinically as an effusion of serous character, found most often at the wrist and hand, where, being constricted by the annular ligament, it is also known as compound ganglion. In its symptoms it does not differ materially from simple serous chronic tenosynovitis. Its progress usually is quite slow, and it may be objectionable to the patient solely on account of the deformity which it causes. Upon incision there is found in addition to the serous exudate a formation of miliary tubercles upon the lining of the sheath. If in addition we find the so-called "rice bodies," we are dealing with the second form. These may vary greatly in size and number. Usually this is in inverse proportion. These bodies derive their name from their resemblance in size and color to grains of boiled rice. They are frequently smaller, however, and, on the other hand, the writer has removed from the palmar sheaths a number of the size of large cherries. For this reason they were easily palpated before incision was made. This is, however, not usually possible, for the reason that abundant serous distention is often present, and because such large size is exceptional. There is commonly imparted to the examining hand a characteristic sensation akin to crepitation, but to be distinguished from it. The fluid may be sufficient to make these bodies impossible of recognition without incision.

The formation of *fungous granulation tissue* upon the serous lining of the sheath and even upon the tendon itself is the distinguishing mark of the third variety. This tuberculous tissue is identical with that found in "joint fungus," and gives rise to doughy, elastic swellings of the sheaths. It is distinctly less benign than the preceding forms, inasmuch as the tubercles are actively disintegrating. The peritendinous structures are, therefore, soon involved; caseation, liquefaction, and the formation of fistulæ are apt to be observed in rather rapid development. Secondary involvement of neighboring joints may occur. This variety, in contrast with the other two forms, causes marked disability from the first, and is frequently very painful. If the disease is allowed to progress, the contiguous structures may suffer to a great extent; the swelling becomes very great, and amputation may become necessary as a last resort. On the other hand, if employed before such extensive spread has occurred, radical operative measures are almost invariably successful if sufficiently thorough. Treatment by

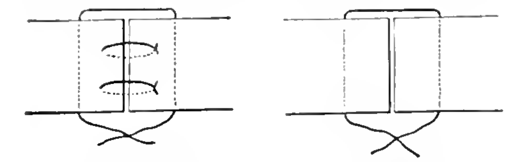

FIG. 4632. FIG. 4633.

FIGS. 4632 AND 4633.—Suture of Divided Tendons.

iodoform injections has not proved satisfactory in this country, although much lauded by some European authors. In the hygromatous form, evacuation of the rice bodies and fluid with scraping of the sheath is, as a rule, all that is required. In the fungous form it is best to remove all infected tissue, and, therefore, to practise the complete extirpation of the tendon sheath. This is usually followed by complete restoration of function if aseptic healing is obtained.

Beck (*N. Y. Med. Journ.*, p. 705, 1901) has described a chronic inflammation of the tendons and tendon sheaths of the hand characterized by the formation of granulation tissue and chalky deposits; he has named this tendovaginitis prolifera calcarea.

INJURIES OF TENDONS.—*Dislocation of tendons* occurs as a rather uncommon accident, and in most of the reported cases the peronei tendons were concerned. After a traumatism to the foot, usually of the kind spoken of as sprain, great disability of the foot is observed, and the tendon of the peroneus longus, with or without that of the brevis also, is found to have slipped from the groove behind the external malleolus, and may be felt as a prominence in front of it. The replacement by manual pressure and retention by means of a crescentic pad and adhesive strips are easily accomplished. In most of the reported cases, however, recurrence of the luxation has occurred, and on this account operations of narrowing the sheaths or deepening the bony groove have been successfully done. Shaffer (Fitzhugh, Trans. Am. Orthop. Assn., 1902) holds the accident to be due to a shortened condition of the gastrocnemius and peroneal tendons. In three cases cure was obtained by stretching these by means of his traction shoe.

Dislocation of the long head of the biceps has been described in a few cases, but on anatomical and experimental grounds there is cause for doubting the possibility of this.

Subcutaneous rupture of tendons occurs rather frequently and may be due to unusually violent muscular action. In some cases it would appear that a pathological condition of the tendon or the neighboring structures was to blame. The rupture usually occurs near the union with the muscle belly or at the bony attachment of the tendon. It is ordinarily felt as a sudden snap with disability, due to loss of function of the affected muscle. Often the gap in the course of the tendon can be felt, and the muscle itself is more prominent than usual on account of its contraction. Although fixation of the limb in such a position as will tend to approximate the torn ends often secures satisfactory healing, it is not wise to depend upon this in the case of important muscles, but rather to approximate and suture the ends through an incision. The tendons most frequently torn are those of the biceps brachii, the plantaris (tennis leg), quadriceps extensor, ligamentum patellæ, and tendo Achillis.

Open wounds of tendons occur very frequently, and especially about the wrist and hand. They may be incised or lacerated. When incompletely divided, union will occur without injury to function. When completely divided, retraction of the muscular end takes place; the ends become adherent to the sheath, and union between them does not occur. Exception to this must be taken in the case of certain operative wounds, such as tenotomy of the tendo Achillis and other tendons of the foot.

Division of the tendons calls for the approximation and union of the ends, and is especially important in the hand, where the usefulness of the member may depend upon it. The muscular end is often difficult to find, and may necessitate considerable enlargement of the wound to make such union possible. Centrifugal wrapping of the extremity with an elastic rubber bandage will occasionally bring the proximal end to view, thus avoiding the necessity of extensive incision. Suture should be done with silk or catgut (chromicized). The sheath may often be sewed over the tendon. As the sutures tend to tear out, one of the methods illustrated here may be employed to prevent this (Figs. 4632 and 4633).

When secondary suture must be done, *i.e.*, after the external wound has healed, it may be extremely difficult or even not feasible to find the proximal end. In this case tendon transplantation has been done (*vide infra*). The proximal end having been found, it may be impossible to approximate it to the distal sufficiently to make ordinary suture practicable. In this event tendon lengthening may be done by splitting the distal end, as shown in Fig. 4634, or a bridge of silk or silkworm gut may be made, uniting the ends and serving as a framework upon which new tissue is afterward formed. Silk will usually be found preferable for this purpose.

Operations on Tendons.—In addition to those above described, operations on tendons are done for a variety

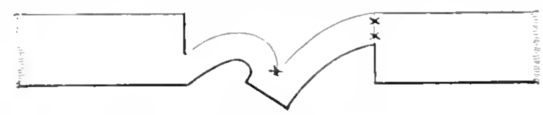

FIG. 4634.—Lengthening of Divided Tendon.

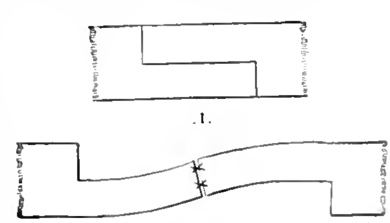
of conditions. The most frequent of these by far is tenotomy, simple division of a tendon. This may be open or subcutaneous. The open operation consists in making an incision parallel with the tendon; the tendon is then divided upon a grooved director in the open wound. The method is one of choice when it is necessary to avoid important structures (*e.g.*, the peroneal nerve in division of the biceps femoris), or where the anatomical situation makes complete division of tendons or muscles not feasible by the subcutaneous method. The muscular variety of wryneck may serve as an example of this; likewise the adductors of the thigh in cases of spastic infantile paralysis. Otherwise, on account of its simplicity and the ease and certainty of the healing process, the subcutaneous method will be chosen. It may be done from within outward or from without inward. The former is the method of choice. The tenotome is a knife with a short blade (1.5 to 2.5 cm.) at the extremity of a long shank (2 to 2.5 cm.), and may be pointed or blunt. The length of the blade should equal the width of the tendon to be cut. An assistant holding the part so as to put the tendon on the stretch, the operator feels for the edge of the tendon and inserts the tenotome behind this with the flat of the blade parallel to the tendon. The tenotome is then pushed through until its point is felt on the opposite side. The edge is then turned toward the tendon, and the



A.

B.

FIG. 4635. Lengthening of Tendon. (Plastic tenotomy.) A, Incision to be employed in dividing the tendon; B, mode of suturing the divided ends.

division is made by a sawing motion. The tendon is felt to yield suddenly and often with an audible snap. The knife is then withdrawn and the minute opening is closed by pressure with a compress of gauze.

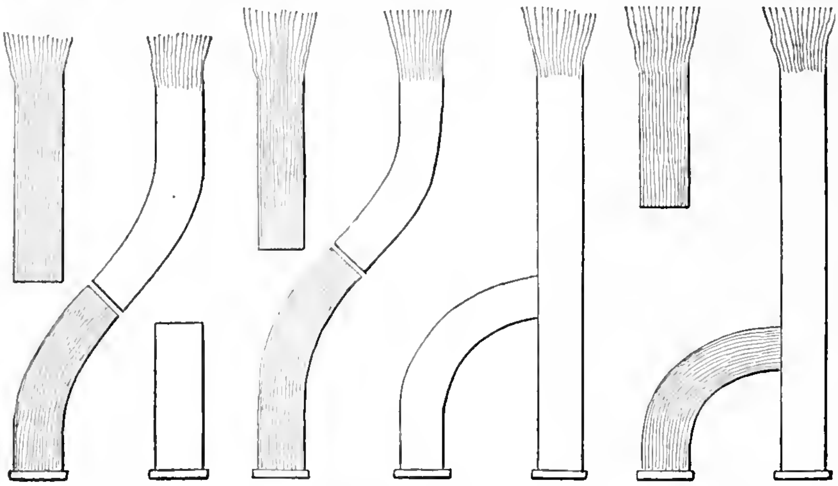


FIG. 4636. FIG. 4637. FIG. 4638.

FIGS. 4636, 4637, AND 4638.—Methods of Functional Transfer. (After Vulpius.) Shading represents paralyzed tendon.

The operation should be done with all aseptic precautions. The wound in the tendon heals by the organization of the blood clot between the divided ends; these soften and become fused with the new fibrous tissue. For some time this has the appearance, both gross and microscopic, of scar tissue. After about three months the new tissue can scarcely be distinguished from the old. Immediately after the division of the tendon the necessary correction in the position of the part is made, and fixation is usually accomplished by plaster of Paris applied over the aseptic dressing. The operation is most frequently done upon the tendo Achillis for clubfoot, either congenital or paralytic; the tibialis posticus and anticus, and the plantar fascia are often divided for the same purpose. Tenotomy may be indicated for the lengthening of any contracted muscle, or when it is desirable for any reason to exclude the action of a muscle, *e.g.*, the tendo Achillis, in the correction of anterior bow-leg.

In some instances, and especially in spastic paralysis, the overcorrection of deformity causes such extensive separation of the divided ends of a tendon that their subsequent union may be in doubt. For the avoidance of this, plastic tenotomy or tendon lengthening is often done. An incision is made over the tendon, which is then split longitudinally for a distance equal to the amount of lengthening desired. Incisions are then made at right angles to this at either extremity of the longitudinal cut and in opposite directions (Fig. 4635, *B*). The figure shows the method of uniting these flaps. For the tendo Achillis, Bayer has proposed a subcutaneous method in place of his original plastic tenotomy. This consists in cutting through half the width of the tendon above and below subcutaneously. Upon making forcible dorsal flexion of the foot the tendon will now split lengthwise and the effect be the same as in Fig. 4635. It has the additional advantage of avoiding adhesion between tendon and sheath. The writer has done the operation repeatedly with satisfaction.

The greatest advance in tendon surgery during the last twenty years has undoubtedly been in the field of tendon transplantation. In this operation the whole or a part of one tendon is engrafted upon or united with the whole or a part of a second tendon. In this way we may either transfer the function of the one to the other, or divide it between the two. The essential indication for performing the operation is a disturbance of the equilibrium between the muscles controlling a joint. This may be due to paralysis or weakening of certain of them, or, in some instances, to the excessive activity of others. It is, of course, assumed that this disturbed equilibrium is incapable of spontaneous recovery or not to be corrected by simpler means. The feasibility of the procedure depends, moreover, upon the persistence of a certain total of muscular power, and its success will to a considerable degree be measured by the amount of this. Before proceeding to describe the technique of the operation and the various combinations from which we may choose, it will be well to discuss in some detail the indications for its performance. In doing so, indebtedness is acknowledged to the admirable monograph of Vulpius ("Die Sehnenueberpflanzung," etc., Leipsic, 1902).

The first group of cases to be considered as calling for tendon transplantation comprises those in which the muscular disability is of traumatic origin. The traumatism may involve the muscles directly, as by incision or subcutaneous rupture of the tendon, or, indeed, the loss of the tendon by suppuration or injury. Tendon transplantation should be considered for these cases, however, only when a very long time has elapsed since the injury, making the finding of the central end of the tendon exceedingly difficult or impossible, or rendering it likely that the muscle belly has degenerated to such a degree as to unfit it for use. Otherwise tendon lengthening by the plastic method, as before described, or by means of silk strands, should be considered the ideal. Traumatisms of peripheral nerves, such as the musculo-spiral, in which for similar reasons direct repair is not feasible, may also call for tendon grafting. In all of the beforementioned conditions it is to be borne in mind that tendon grafting is a procedure of second choice, to be done only in the event that direct repair by suture is excluded.

By far the most frequent indication for the employment of transplantation of tendons is paralysis of central origin, either spinal or cerebral. The largest class of these cases results from acute anterior poliomyelitis. It is well known that in such cases the paralysis, quite extensive to begin with, is recovered from during the first few months, so that after a year has passed there remains an involvement, of more or less circumscribed extent, of permanent character. We have then to deal with paralysis of certain muscles or groups of them, the remaining ones of the limb possessing normal power. In this event deformities are likely to develop, unless prevented by treatment, because of the lack of antagonism to the normally innervated muscles. These latter being made to share their power with the paralyzed muscles, equilibrium may be restored to the affected part, deformity prevented, and a considerable gain in the total power achieved by adaptation to the increased function. In those unfortunate cases in which flaccid paralysis of all the muscles of a part persists, or in which the paralyzed greatly overbalance in number and strength the unaffected ones, the operative stiffening of the joint, *i.e.*, arthrodesis, offers far more than operation upon the tendons. On the other hand, it has been observed after tendon transplantations that muscles which were paretic or atrophic from lack of use have under the new functional conditions regained their usefulness, so that the sum total of muscular power, after operation, was considerably above what was anticipated. Whether in a given case arthrodesis will be preferred to transplantation or treatment by braces to either of these, will depend largely upon individual experience and judgment. Occasions, furthermore, arise in which these methods may with advantage be combined. The various forms of spastic paralysis, both spinal and cerebral, have also been treated by tendon transplantation with signal benefit. Of the cerebral cases only those should be chosen, however, in which the mental condition of the patient is good.

In the treatment of paralytic deformities already developed, the overcorrection of these should, as a rule, precede the operation upon the tendon. In any paralytic case transplantation should be considered only when likelihood of spontaneous improvement is no longer apparent.

Finally, the operation has been done for a number of deformities not of paralytic origin. Thus, to prevent the tendency to flexion after arthrectomy, or excision of the knee, or that which frequently occurs after the cure of tuberculosis or other severe arthritis of this joint, implantation of the hamstrings into the quadriceps tendon has been done with success. Likewise in severe cases of pes valgus or plano-valgus the operation has had its value demonstrated.

In order to decide upon a plan of operation it is necessary to know which muscles are paralyzed and which are not. This must be decided by careful observation of the patient and the voluntary movements of the part, and also by the electrical reactions. It is not to be forgotten, however, that the atrophy of disuse in certain muscles, caused by the paralysis of some of the more important ones of the part, cannot be recognized in this way; but for this purpose ocular inspection of the muscle substance is necessary. In contrast to the dark red of the normal, the paretic fibres of inactive but non-paralyzed muscles are pink of varying shade, while the paralyzed ones look yellow or yellowish-white, according to the amount of fatty degeneration. The complete design of the operation may have to be deferred for these reasons until such inspection has been made.

In the performance of the operation perfect asepsis is a prerequisite. When the tendons to be united are near to one another, a single incision parallel to them may suffice. When they are separated by a somewhat greater space, a slanting cut may be advantageous; but when the distance is considerable multiple incisions may be called for; these may also need to be made quite long for the inspection of the muscular substance. The tendon sheaths should be treated as conservatively as possible.

The combination of the tendons may be done in a number of ways. The simplest method is by lateral anastomosis. In this the continuity of both sound and paralyzed tendon is preserved; both are freshened and united by lateral apposition; tension being secured by drawing the paralyzed tendon proximally, the sound one in the opposite direction. The method is available only when the tendons lie in contiguity.

The second method is that of functional transfer (Figs. 4636, 4637, and 4638). In this the sound tendon is cut through completely, and is sewed to the whole or a part of the paralyzed tendon. This presupposes that the sound tendon is either useless or even harmful in its action, as by it the peripheral stump of the tendon is unused. This fault may, however, be overcome by uniting the distal end of the sound tendon with a sound neighbor. Finally we have functional partition, in which only a part of the sound tendon is joined to the paralyzed one (Figs. 4639 to 4642). This has the great advantage of conserving the function of the sound muscle through the uninjured part of its tendon. The figures show the methods by which functional transfer and functional partition may be achieved. The shaded tendon represents the paralyzed structure. Which of the methods will be chosen will depend upon the functional importance of the unparalyzed tendon which is to be used; upon its size, *i.e.*, whether a slip may be taken from it large enough to sew securely; and upon other conditions which present themselves at the time of choice. It is always preferable, when possible, to graft tendons of similar function; for example, an extensor upon an extensor. This need not of necessity be done, however. In doing functional partition it is desirable that the split in the tendon be made as near the muscle substance as possible, and that it be continued by blunt separation of fibres into the muscle belly for a short distance. This is done in order to achieve as much functional differentiation of the two parts as possible.

While the tendon is being cut through it should be held by means of clamp forceps, so as to prevent retraction into its sheath after complete division. In displacing the tendon from its old into its new position it is desirable that it shall be placed under the deep fascia, if possible, in order to minimize the likelihood of adhesions. Drobnik's suggestion to pass the tendon beneath the other tendons of the part may, however, be regarded as involving an unnecessary amount of disturbance. It is highly important that the new course of the tendon be a fairly straight one; this requirement should be borne in mind in choosing the tendon and the point at which it is cut

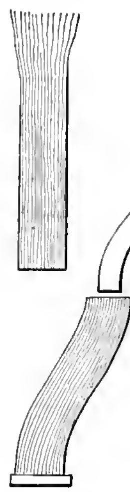

FIG. 4639.

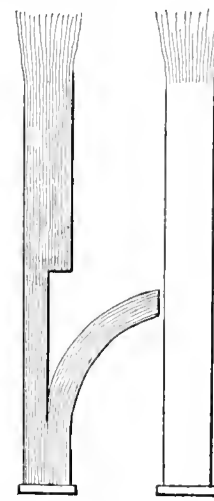

FIG. 4640.

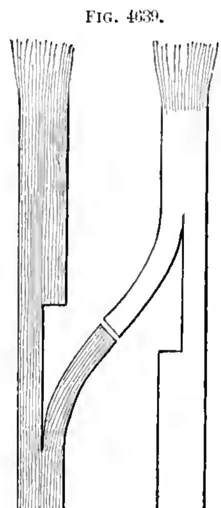

FIG. 4641.

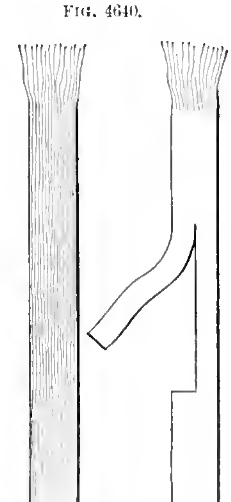

FIG. 4642.

FIGS. 4639 TO 4642.—Principal Modes of Functional Partition. (After Vulpius.) Shading represents paralyzed tendon.

through. In grafting extensors upon flexors, or the reverse, the tendon may in the forearm and leg be carried through the interosseous space instead of around the limb.

The suture should be made under a certain amount of tension, and should be capable of withstanding considerable force. This is best accomplished, ordinarily, by passing the end of the divided tendon through one or even two buttonholes in the other tendon and securing it by a number of sutures. When two divided ends are to be joined, this is done, as above described, under tendon suture. Silk is by all means the best material to use for the suture, as it can be made truly aseptic, and will retain its strength sufficiently long. In a small proportion of cases sutures will afterward work their way out without jeopardizing the result of the operation.

In order to satisfy the two rules, that the tendon suture should be under tension and that it should be done under slight overcorrection of any pre-existing deformity, it will often be necessary to do tendon lengthening on some contractured muscle, such as the tendo Achillis, and tendon shortening on others. Lengthening is done by means of the plastic tenotomy above described (Fig. 4635), while shortening is usually best accomplished by taking a fold in the tendon and maintaining it by sutures.

The proposals of Lange and Wolff to fasten the end of the active tendon into periosteum or bone, instead of into the paralyzed tendon, would seem to involve unnecessary complication, and the more so since the results of these procedures have not been shown to surpass those of the older ones. Lange's plan of using silk strands to connect a sound tendon with a bony insertion in order to avoid the necessity of incising or splitting the tendon has been proved by him to be perfectly feasible. It might be employed with advantage where the tendon graft cannot be made of sufficient length.

The operation upon the tendons having been completed, it is well to attempt to bring the wounds in the sheaths together, or at least to sew the fascia over them. In closing the skin wound drainage had best be dispensed with if possible. The part should be fixed in a plaster-of-Paris dressing, applied over the aseptic bandage; this should hold the joint in a neutral position, *e.g.*, midway between flexion and extension. In the absence of wound infection, the original dressing should be allowed to remain for from six to eight weeks. Suppuration will usually place the result in great doubt. It is not, however, incompatible with a successful issue. It is best to maintain the patient in complete recumbency for at least one month.

After the removal of the fixation dressing, warm baths, massage, passive and active, as well as resistive movements, must be employed with energy and skill if fullest success is to be obtained. In many cases a light brace should be worn during the first few months, so that the act of walking may not tax the muscles too greatly. This is especially true of cases in which a deformity had been corrected.

The number of combinations which may be made in the performance of tendon transplantations is so great that space forbids mention of them in detail. For this reason only a few of the commoner ones are given as examples.

Paralysis of Tibialis Anticus and Tibialis Posticus.—The foot is in position of equino-valgus. The extensor hallucis is cut through and the proximal end is sewed to the tibialis anticus. A slip is taken from the extensor communis and sewed to the tibialis anticus. The distal end of the extensor hallucis is attached to the extensor communis. The tendo Achillis is lengthened, and the peroneus longus is grafted upon the tibialis posticus.

Paralysis of Gastrocnemius.—The foot is in position of calcaneo-valgus. The proximal ends of peroneus longus, flexor digitorum, and a slip from the tibialis posticus are implanted upon the tendo Achillis, which itself requires to be shortened. The distal end of the peroneus longus may be attached to the tendon of the peroneus brevis.

Paralysis of Extensor Communis and Peronei.—The foot is in position of equino-varus. Redressement of the deformity. Extensor hallucis sewed to extensor communis digitorum. Tibialis posticus severed and proximal end attached to peroneus brevis. A slip from tendo Achillis is attached to the peroneus longus.

While tendon transplantation is by all means to be considered a very great advance in the treatment of partial paralysis and of paralytic deformities, unreasonable things should not be expected of it. The most satisfactory results by far are obtained when only one or two muscles are paralyzed, and here the cure may under favorable conditions be practically perfect. When a number of important muscles must be substituted for, much less is usually accomplished. A better position of the limb, making the wearing of apparatus easier, because of simpler needs for it, is all that is frequently accomplished, and it is likely that in some cases arthrodesis would be of more beneficent effect. The success of transplantation depends, however, not only upon the selection of the proper muscles for grafting and a correct operative technique, but in no less degree upon attention to even the minor details of the after-treatment. The full benefit of the operation is usually not to be observed until some months afterward, and the total improvement is sometimes not gained until a period of as much as two years has expired. Sometimes benefit from the operation is found to be transitory; a few months afterward the patient is found to be in the old condition. In this case careful investigation will sometimes disclose the cause of failure in improper selection of energizing muscles, and one may with hope of success resort to secondary operations. *Albert H. Freiberg.*

TERATOLOGY—derived from the Greek word τερατολογια (τερας, monster + λογια, tell)—in its broadest application is that department of biology which treats of the malformations or abnormal growths in both the animal and the vegetal kingdom. In the more restricted and usual sense of the term, as suggested by the elder Saint-Hilaire, in 1822, teratology includes the consideration of the graver malformations resulting from deviations in the normal development of man and other animals occurring at some period before birth.

It is evident that no sharp demarcation can be drawn between the many slight developmental variations giving rise to the numerous anomalies, or *hemiterata*, affecting various parts of the body and the more serious defects appropriately classed as malformations; with the latter, however, is associated the existence of disturbances of form and function which more or less profoundly affect the well-being of the organism.

Malformations may be grouped as *primary* and *secondary;* the former include those produced by arrest or deviation of the fundamental processes of development by which the animal body, or its parts, originates; the latter embrace those that result from disturbances of organs or parts, the early development of which has progressed normally until adversely impressed by some secondary influence.

Malformations presenting marked change or distortion from the normal appearance of the embryo or fœtus are termed *monsters*. In these the external characteristics are usually associated with structural defects of such gravity that the organism is incapable of maintaining an independent existence after separation from the sources of maternal nutrition. A conspicuous exception to such inability is seen in double monsters, which, notwithstanding their striking peculiarities, sometimes, as in the case of the famous Siamese twins, live, grow, and even thrive for years.

History.—An intelligent interpretation of malformations is so dependent upon an adequate knowledge of the processes of normal development that the evolution of teratology from the crude and fanciful speculations of the past into a recognized department of biology, founded upon a sound and rational basis, is largely the record of the progress of embryology itself.

The appearance, in 1759, of the epoch-making *Theoria generationis* of Caspar Friedrich Wolff marks the beginning not only of a true conception of normal development, as a progressive differentiation and specialization of a primarily simple germ-mass, but likewise of a just appreciation of the causes leading to abnormal formations.

From the earliest times the occurrence of congenital malformations may well be imagined as having arrested the attention and exacted the speculation of philosophers of all ages; objects of such deep general interest could not escape the keen scrutiny of Aristotle (384-332 B.C.), and to him we are indebted for the earliest discussions of the causes and the manner of production of such abnormalities.

Notwithstanding the interest with which these defective beings were regarded, over two thousand years elapsed before their true nature began to be suspected during the early half of the eighteenth century. Previous explanations of the production of monstrosities consisted of confused and fanciful assumptions, often grotesque in their absurdity, in which supernatural influences, the benign or baneful exercise of divine power, the impressions wrought by heavenly bodies, the blighting influences cast by unholy spirits and by witches, sexual congress with the lower animals or with Satan himself—"coitus cum diabolo" being an accepted factor even as late as Martin Luther and Ambrose Paré—all found accredited place in the category of potent causes of monstrous births. A detailed consideration of such idle speculation need not here detain us; the reader interested in a fuller account of these curiosities of medical literature may be referred to the interesting *résumé* of past theories contained in Ballantyne's paper on "Teratogenesis."[1]

Following, although tardily, the more accurate trend of anatomical investigation inaugurated by the genius of Vesalius and the enthusiasm of his pupils, the progress of teratology during the seventeenth and eighteenth centuries is marked by the passing of old traditions and the dawn of a rational conception of the significance of malformations as evidenced by the increasing number of accurate descriptions of these variations by competent observers. An adequate interpretation of malformations was manifestly impossible at a time when the fundamental facts concerning normal development were still to be recognized.

The discovery of the mammalian ovum by de Graaf, in 1672, and of the spermatozoa by Hamm, three years later, supplied the basis for the bitterly contested discussions of the two factions—the "ovists" and the "animalculists"—which, however, met on common ground in the acceptance of the doctrine of "evolution" which assumed that gestation resulted in the expansion and unfolding of the perfectly developed body, preformed but of infinitesimal size. These principles when directly applied to the explanation of malformations, as they were by many, led to the conclusion that such defects must result from malformed germs—an admission irreconcilable with the generally conceded adaptability to purpose of nature and a divine Wisdom. In order to meet these objections, the influence of mechanical disturbances, as well as of external pathological conditions, upon the unfolding germ was assumed by the more conservative. Even the philosophical Haller failed to appreciate the importance of the views advanced by Wolff, who, recognizing the fundamental truth that each new being is formed by individual development and differentiation of the primary simple germ, declared malformations to be the results of abnormal variations of the formative energy which under favorable conditions produced the perfect being. While in the main accepting the correctness of the then current doctrine of preformation, Haller presented for the first time a critical analysis of the relation of the known causes of abnormal development to the facts established by observation as gleaned from his own rich experience; he must be regarded, therefore, as one of the founders of scientific teratology.

The closing years of the eighteenth century, and the opening decade of the next, witnessed further advances in the study of malformations in the accurate investigations into the anatomical peculiarities of many abnormalities by Sömmering, Autenrieth, Tiedemann, Blumenbach, and others; Sömmering in particular was fortunate in recognizing the fact that congenital defects were not capricious aberrations, but that in their production they followed definite laws.

The services of Meckel to embryology in securing to Wolff's later papers their merited recognition, by translation into German, were also shared by teratology, since his keen appreciation of the truth of Wolff's "Epigenesis," as opposed to the long-accepted evolution theory, enabled Meckel to regard the production of malformations from an advanced standpoint. As an ardent believer in the dynamic causes of malformations, Meckel sought to explain the majority of defects as the result of disturbances of formative energy, attributing to an early arrest of development the prominence which his own researches suggested.

In 1822, four years after the completion of Meckel's "Handbuch der pathologischen Anatomie," the name of Saint Hilaire appears which, represented by father and son, has become inseparably associated with the study of congenital defects. The "Traité de Teratologie" of the younger, Isidor Geoffroy, Saint Hilaire, published in 1837, presented a most elaborate and systematic consideration of malformations in which the various forms of deviation are described and grouped with such completeness that even at the present day n ny of the features and names of St. Hilaire's classification find recognition by the latest writers. Although influenced by the opinions of his father to regard mechanical influences as the most potent cause in producing malformations, the fuller appreciation and the emphatic statement of the truth that certain typical forms of variation are continually repeated are among the benefits derived from the teachings of this eminent French teratologist.

Among the immediate results of the establishment of the cell doctrine by Schleiden and Schwann, in 1837, were not only renewed investigations and rapid advances pertaining to normal development, but also more searching inquiries into the mode of production of malformations in the light of these newer views. The contributions of Bischoff (1842), Vrolik (1849), Panum (1860), and Förster (1865) mark the beginning of a new era in teratological literature; the last-named author, in particular, proposed a classification upon an embryological basis which, in a modified form, may serve the purposes of today. Among the more recent systematic works on teratology may be mentioned those of Ahlfeld (1880), Taruffi (1881-95), Hirst and Piersol (1891), Guinard (1893), and Marchand (1897).

The deep interest which the causation of malformation has always excited could not fail to suggest attempts to produce artificially monstrosities as aids in solving the problems connected with the mode of production of these variations. Even before the appreciation of the fundamental truth that malformations arise as disturbances and deviations of the normal processes of development, the elder Saint Hilaire succeeded in producing abnormalities by incubating hens' eggs placed in unusual positions, thus meriting the distinction of being the founder of experimental teratology, to the results of which we are indebted to many most suggestive and important data. Liharzik, Panum, Dareste, Schrohe, Koch, Gerlach, O and R. Hertwig, and Richter are among the investigators whose experimental studies yielded positive proofs of the disturbing effects of mechanical, chemical, thermal, and other influences. Within the last ten years the important experimental studies of Roux, Born, Driesch, Wilson, O. Schultze, Windle, Morgan, Schaper, and others have added much valuable information relating to embryological mechanics and to the formation of developmental variations.

It will be seen from the foregoing brief historical sketch that the advancement of teratology as a science may be divided (according to the predominating influences) into three periods:

1. The descriptive—embracing the last half of the eighteenth and the first third of the nineteenth century, when the systematic grouping of the various malformations was based upon the apparent relationship, as exhibited by the characteristics of the completed defects.

2. The morphological—during which the anatomico-embryological details chiefly claimed attention.

3. The experimental—including the last ten years, during which the causation and the mode of production have been the subjects of inquiry rather than the structural peculiarities of the malformations. It is to the further achievements along the lines of experimental investigation that we must look for the advances in accurate knowledge necessary to place teratology upon a satisfactory plane as a department of biology.

In the limited space allotted to this article it will be impossible to present more than a brief account of the more important malformations occurring in the human subject. For a more detailed consideration of the particular defects, the reader must be referred to the special papers to be found in the publications noted at the end of this article.

Causation.—The etiology of malformations in many cases is still a matter of uncertainty; the causes, however, may be divided in general into two groups—*external* and *internal*. The latter, in contrast to external causes, may be held responsible for the production of spontaneous malformations in which influences acting from without are excluded; they comprise the defective constitution of the germ-plasm, whether the latter be modified by the inherent peculiarities of one or both parent cells, by pathological changes affecting the embryonic organism, or by impressions due to heredity or atavism.

The occurrence of defective conditions of the parental germ-cells, whether of father or mother or of both, is more a matter of *a priori* assumption than of positive demonstration, since it is impossible to detect structural variations which account for the often far-reaching impressions produced on the embryo.

The influence of heredity—whatever the limitations of our intimate understanding of the phenomena—in the production of malformations has long been recognized in those cases in which particular defects, as supernumerary fingers and toes, harelip and skin pigmentation, occur in certain families through successive generations. Even graver abnormalities, including hypospadias, imperforate anus, spina bifida, microcephaly, and partial absence of limbs, seem influenced by transmitted predisposition. An unbroken sequence of generations may be wanting, since the defects may be absent in one generation and again appear in the next, or a "reversion" may occur to an abnormality presented by some ancestor several generations removed.

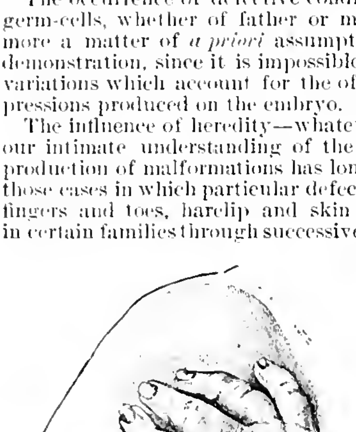

Fig. 4643.—Distortion of Upper Extremity Resulting from Amniotic Pressure. (Ziegler.)

The responsibility of one parent for the inherited defect has been repeatedly shown in families where the children of one father by two or more wives, or, conversely, those of one mother by different husbands, have presented similar malformations. A remarkable case in point is recorded by Meckel,[2] in which two children of a man by his first wife had harelip; of four children by his second mate, two had the same deformity, while a third had cleft palate. Two relations of the father also had harelip. Gade[3] reported the case of a woman who had given birth to three anencephalic monsters.

Notwithstanding the important investigations of recent years relating to the details of the union of the chromatin contributed by the male and female germ-nuclei that have given to our knowledge of fertilization an almost mathematical precision and supplied an accurate morphological basis for our understanding of heredity, the inscrutable variations in the ultimate constitution of the chromatin upon which depend the transmission of inherited characteristics must still remain subjects of speculation.

Pathological changes affecting the early embryo are sometimes indistinguishable, in their consequences at least, from true formative disturbances, since both may result in the arrested development and death of the embryo. Defective nutrition, whether due to diseased conditions of the maternal tissues or to defective development of the early circulatory system of the embryo itself, is responsible for the loss of many products of conception—probably of a far larger number than is usually appreciated, since these may be thrown off in the earlier weeks of gestation without attracting attention. The aborted "moles" so frequently encountered are the malformed and partly absorbed embryos of later, but still early, stages; the disproportion between the size of the embryo and the duration of pregnancy, so conspicuous in many cases, is accounted for by the fact that the death of the embryo takes place some time prior to its expulsion. In not a few instances, in which death occurs at a very early period, absorption has been so complete that even the most careful examination fails to locate the embryo within the enveloping sac.

We are indebted to His[4,5] for the first comprehensive study of these defective forms which, according to this authority, constitute at least forty per cent. of all early abortions. Giacomini[6] regards this estimate as too low, and declares that in less than twenty-five per cent. of abortions during the first month the embryo presents normal development. The last-named writer divides these abortive products into two chief groups: 1, the embyro is present; 2, the embryo is absent. When present, the embryo is represented by (*a*) atrophic forms, or (*b*) nodular malformations. When absent, the disappearance of the embryo may be due (*a*) to absorption, either with or without the retention of the fetal appendages, or (*b*) to complete or partial escape from its enclosing sac.

Mall[7] has also contributed an instructive paper relating to early malformed embryos. In all described, some fifty in number, he regards the abnormality as either primarily of the embryo or of the chorion. The term "vesicular" is suggested instead of His' nodular forms, all of which are earlier than the second week. Mall concludes that the cells which so conspicuously infiltrate the tissues of such malformed embryos are the blood cells that migrate from the vessels, which latter are left enlarged and empty. After the early formation of the amnion, the embryo may die while the amnion, chorion, and umbilical cord continue to grow for a time, thus accounting for the discrepancy between the development of the membranes and of the product of conception which may undergo partial or complete destruction. In certain cases the supposed vesicular embryo is really the remains of the yolk sac.

External causes adversely affecting the development of the embryo include *mechanical influences*, as traumatism and pressure, *physico-chemical influences*, as variations of temperature, electricity, deficient oxygen, toxics, and *maternal influences*. External violence, when not too overwhelming in its immediate effects, may bring about arrest of development and subsequent malformation by causing an impaired nutrition in consequence of the separation between the ovum and the maternal tissues due to extravasation of blood. The results of such nutritive disturbances may be death and subsequent expulsion of the embryo, or a malformation which may be retained until the termination of gestation.

Pressure is a potent source of defective development; and even when of slight degree, if long continued and exerted at an early period, is capable of producing profound changes in the young fœtus. Conspicuous examples of malformations due to such causes are seen in abnormalities of the extremities, congenital luxations and club feet, in the production of which unusual relations of the amnion, or malposition of the fœtus in utero, must be assumed as common sources of the undue pressure. Joachimsthal[8] further refers certain examples of spinal curvature, deep constrictions on the head, and flattened nose to such influences. The pathological conditions of the fetal membranes, particularly of the amnion, may be responsible for pressure-defects in cases in which the available space for the developing fœtus is reduced by hemorrhages either within or between the membranes.

Many malformations may be properly attributed to arrested or disturbed development induced by pressure in consequence of failure of the amnion to keep pace in its expansion with the growth of the fœtus. The close relation between the tubular amniotic envelope and the young human embryo, especially at its cephalic end, renders abnormal diminution of the amniotic space in the early stages a serious matter for the delicate product of conception. Under such unfavorable conditions profound changes may occur, which, when involving the head, may lead to defective development of various segments of the brain, the eyes (*cyclopia*) or the parts normally formed from the visceral arches. Certain types of deformities of the skull (*cranioschisis*) and of the spine (*rachischisis*) are probably expressions of later influences due to amniotic pressure.

Likewise the development and differentiation of the caudal end of the embryo may suffer and the immature lower limbs may remain stunted (*phocomelus*) or unformed, or early be so blended that their future development gives rise to a composite member (*symelus*).

In certain cases there is evidence that the pressure has been only temporary, the amnion after a time assuming a normal relation to the fœtus. Rarely the obliteration of the amniotic sac is only local, the membrane being closely applied to the fœtus over portions of its surface, while in others the amnion is separated and removed by accumulations of the amniotic fluid. Where tightly applied the investing membrane sometimes undergoes atrophy to such extent that the embryo appears to, or actually does, lie partially uncovered.

Amniotic adhesions are productive sources of malformations, especially of those parts, as the head and the extremities, which present prominences favorable to the attachment of the investing membrane during the early period of gestation when the amnion lies closely related to the embryo. The fact that both the exterior of the latter and the inner surface of the amnion are covered by the same layer, the ectoblast, is favorable to union of these surfaces when brought into unusual intimacy. Such adhesions may remain limited, or, when favored by mechanical influences, may become more extensive and firm. When, on the other hand, the amnion is later removed from the embryo, the adhesions may be reduced to a few delicate and attenuated strands, as occasionally seen attached to the fingers and toes. Sometimes the constriction due to an encircling band of amniotic tissue leads to amputation and loss of a larger or smaller portion of one or more limbs. Ridlon[9] describes a case exhibiting congenital amputation of both legs at the knee and of the left arm at the elbow. In another he noted a constriction around the middle finger on one hand; on the other the corresponding finger beyond the proximal phalanx was represented by a mere thread. On both feet the distal phalanx of the great toe and the distal and middle phalanges of the second toe were amputated, the third digits being also imperfect. The fact that the separated parts are never found is explained by their maceration and disintegration after constriction, since such amputations occur at a time while the limbs are still small and immature. Not infrequently the amniotic adhesions may disappear as gestation advances, and at birth their former existence may be indicated only by

FIG. 4644.—Results of Amniotic Adhesions. (Marchand.)

scar-like markings. It is often difficult or impossible to distinguish between primary unions and the results of secondary adhesions due to inflammatory processes, although according to Tesdorpf[10] the blood-vessels so characteristic of the latter are wanting in the simple primary attachments.

The prominence and irregularity of surface presented by the head offer especially favorable localities for amniotic adhesions. These may lead to profound disturbances in the development of the skull and brain, as well as to the more common defects in the formation of the face due to interference with the closure of the various clefts between the processes and arches which normally take part in completing the face. The unusual traction exerted by an attached amniotic fold may give rise to extensive facial clefts, or if attached in the orbital region defects involving the palpebral opening, together with those of the eyelid or eye, may occur. The accompanying illustration from Marchand is a remarkable exhibition of the defects produced by amniotic adhesions, including partial exencephalus, oblique facial cleft, disturbed and imperfect development of the right eye. A firm band connects the head with the thorax in consequence of which attachment closure of the ventral body wall has been incomplete. Additional manifestations of amniotic adhesions are seen in the constricted condition of two fingers of the right hand and the tail-like appendage attached in the lumbar region.

Ahlfeld[11] has pointed out that the oval areas of defective integument occasionally seen on the head are attributable to limited amniotic adhesion of tubular form.

The effects of *physico-chemical influences* upon development have suggested important themes for the experimental investigator who has subjected the ova of the lower types, as birds, amphibians, and fishes, to variations of temperature and to the action of chemical substances and of electricity. Interesting as the results of such investigations may be in connection with experimental teratology, it must be pointed out that our knowledge relating to the effect of these influences upon the human embryo is for the most part conjectural. The well-known adverse effects of certain febrile conditions of the mother in frequently producing abortions are attributable by no means exclusively to increased temperature, nor have we any evidence that the latter cause may produce malformations. The disturbances of development which follow artificially induced deficiency in the supply of oxygen in the case of the bird's ovum, may be assumed as taking place in the higher forms and man whenever the normal balance between the necessities of the fœtus and the maternal supply of oxygen becomes impaired, either by reason of imperfect connections between the fetal membranes and the maternal tissues, or of stasis and venous congestion of the maternal circulation; although such conditions may result in the death of the fœtus, we have no evidence that malformations may be so produced. In like manner fatal consequences may follow the introduction of toxic or infectious substances into the circulation of the fœtus.

Maternal Impressions.—The influence of impressions received by the mother during gestation has always been regarded by the laity, and, indeed, by not a few members of the medical profession as well, as a most potent cause in the production of malformations. Nor is it strange that this venerable and deeply rooted superstition should continue to be regarded with favor when we consider the widespread ignorance concerning the normal processes of development which prevails among otherwise well-informed persons. While appreciating the honest convictions of many in the belief of the power of such impressions, and in the sometimes seemingly convincing testimony adduced in support of such views, it must be borne in mind that the teaching of embryology and the verdict of unbiassed critical review of the evidence presented are irreconcilably opposed to such claims. Attention may be called once more to the significant fact that in a majority of cases the affected parts are well advanced in their development before the supposed impression occurs; in fact, not infrequently the developmental deviations necessary to produce the malformation attributed to the influence of the maternal impression take place before the existence of pregnancy is even suspected. Were the instances recorded in which no defective development follows the exposure of the mother to impressions to which malformations are attributed, the overwhelming majority of negative results would do much to lessen the effect now made on the popular mind by the carefully reported cases in which the real or imaginary coincidences are cited as positive proofs of the sufficiency of maternal impressions as a cause of deviations in embryogenesis.

Although, as again emphasized by Ballantyne,[12] it cannot be admitted that an unusual impression upon the mind of a pregnant woman is capable of producing defects in the fœtus closely resembling the object responsible for the impression, there are sufficient grounds for believing that the mental state of the mother may indirectly influence the development of the offspring by inducing changes in nutrition leading to congenital debility, retarded growth, and even death. Conceding that certain defects may result from nutritive changes arising in consequence of profound nervous impressions on the mother, nevertheless, to those familiar with the embryological significance of malformations, the basis of the popular belief in the potency of maternal impressions will appear as depending upon the very natural desire to find an explanation for unintelligible misfortunes in coincidental circumstances rather than upon well established and accurately observed phenomena.

Frequency of Malformations.—The earlier attempts to determine the relative frequency of malformations resulted in widely differing estimates. The most trustworthy figures are those supplied by Winckel,[13] who found in Dresden, covering a period of eleven years, in 10,056 births 156 abnormalities, or 1:64; the same authority, however, records the occurrence of 232 malformations in 8,149 births, or 1:35, in Munich during ten years. The latter proportion agrees closely with the results of Förster, whose observations gave 1:36 based upon the examination of 1,000 cases.

Classification.

All attempts to divide malformations into systematic groups must be regarded as more or less provisional in the present state of our knowledge concerning the mode of their production, since it is evident that an entirely competent classification must be based upon their origin and true nature rather than upon the external peculiarities of the abnormalities. The elaborate classification devised by the younger Saint Hilaire attempted to provide for all forms of variation, but notwithstanding its apparent completeness many incongruities became evident as an embryological foundation for teratology became more secure. The artificial divisions set up by many proposed classifications based upon external characteristics separate abnormalities which are closely related, and, on the other hand, place in intimate relation defects depending upon entirely different causes. The early attempt by Bischoff to formulate a division based upon the embryological significance of the variations was supplemented with greater success by the classification of Förster,[14] in which malformations are considered from the standpoint of their development. More recently Marchand[15] has adopted Förster's classification which, in a modified form, has been likewise followed in this article.

Abnormal Development Affecting the Entire Embryonic Area.—In addition to the disturbances due to pathological conditions of the amnion and the chorion which so often result in the defective development, early death, degeneration and partial or complete absorption of the embryo, already described in connection with the various forms of "moles," the changes affecting the entire embryonic area may be considered as (1) *abnormalities of size*, (2) *abnormalities of position*, (3) *duplicity*.

Congenital Abnormalities of Size. These may be either (*a*) *excessive* or (*b*) *defective*.

1. *Excessive size*, giant growth, or *macrosomia*, is characterized by a general increase of the entire organism which may be manifested at, or shortly after birth, or be developed later, especially about the time of puberty. True giantism is to be distinguished from the excessive size observed in consequence of pathological conditions (*acromegaly*). While slight manifestations from the normal average length (50.5 cm., or about 20 in.) and weight (3,250 gm., or about 7.2 lbs.) of the new-born infant constantly occur, well-substantiated instances in which these figures are exceeded to any marked extent are by no means frequent. Among the instances of new-born children of excessive weight is the case noted by Eddowes[16] of a male child weighing twenty pounds two ounces, and measuring twenty-three inches in length. Dickinson[17] reports the case of a woman whose first child weighed nine pounds, the second twenty, and the third sixteen. Rice[18] mentions a neonatus weighing twenty and a quarter pounds, Baldwin[19] one that weighed twenty-three.

It is worthy of note that children of extraordinary size are usually offspring of parents of average stature. A striking exception is presented in the case reported by Beach,[20] since the father measured seven feet two and one-half inches and the mother seven feet five and one-half inches. Their first child, immediately after birth, weighed eighteen pounds and measured twenty-four inches, while the second turned the scales at twenty-three and three-quarter pounds and was thirty inches long. The assumption of an excessive amount of formative material or genetic force, in an attempt to find an explanation of these instances of unusual growth, must be unsatisfactory, and it must be admitted that our knowledge is altogether conjectural as to the cause of these cases.

Equally uncertain is the etiology of the curious partial excessive growth limited to some particular part of the body, as where one-half of the body, one extremity, one hand, or even a single finger or toe, attains unusual dimensions without participation of the adjacent parts. As with a general giantism, so here, the affected parts may for some time after birth present no unusual characteristic, the tendency to extraordinary growth first becoming noticeable at a later day. These instances of hemihypertrophy must be carefully distinguished from enlargement, the result of inflammatory processes or other pathological conditions.

It may be of interest to note incidentally the excessive stature of a few famous "giants," although it must not be forgotten that in the majority of these individuals the undue proportions are expressions of pathological conditions (acromegaly) rather than true giantism, the conspicuous stature depending largely upon excessive growth of the lower limbs. The accounts of individuals over nine feet in height are to be regarded as apocryphal, very few well-authenticated cases exceeding eight feet. Measurements by Topinard on Austrian soldiers gave eight feet four and one-half inches as the extreme height. The giant Winckelmeyer is said to have attained a height of eight feet six inches. O'Brien, the famous "Irish Giant," whose skeleton was secured for the museum of the Royal College of Surgeons, London, by John Hunter, measured eight feet four inches at the age of twenty-four; his successor, Patrick Cotter, was of similar height.

Women of unusual stature have become famous, from time to time, as "giantesses"; among the most noted of those accurately measured in recent years may be mentioned "Leah," an American, who at nineteen years of age measured seven feet two inches, and the giantess, Miss Marian, eighteen years old, who was exhibited in London as possessing a height of slightly over eight feet. The "Kentucky Giant," Captain Bates, and his wife, the "Nova Scotia Giantess," measuring seven feet two and one-half inches and seven feet five and one-half inches respectively, enjoyed the distinction of having a combined stature of fourteen feet eight inches and of being the tallest married couple known. The excessive size of the children springing from the union of these giant parents has been noted above in the case recorded by Beach. These giants themselves were the offspring, in both cases, of parents of usual stature.

2. The second group of abnormalities of size includes those exhibiting *defective growth*. These may be divided into (*a*) early defects arising from impaired nutrition, represented by the embryos whose arrested growth usually results in death and abortion during the first weeks of pregnancy; (*b*) fœtuses which complete their development, but in which growth has been defective so that at the close of gestation the new-born child is conspicuous for small size, constituting a congenital dwarf.

True dwarf growth, or *microsomia*, in which completed development is associated with insufficient growth, is to be distinguished from the not infrequent cases in which the diminutive size is due to the acquired influence of disease, as rachitis, caries, or inherited constitutional vice. True dwarfs of conspicuously diminished stature are extremely rare, their essential differential characteristic being that all parts of the body, including the head and the brain, are properly proportioned, although reduced in size. In the dwarfing due to pathological influences, on the contrary, the reduction in size is confined to certain parts, as exemplified in the shortened extremities of rachitic subjects. Such disproportion results in marked preponderance of the unaffected members, as often observed in the unduly large head of children affected with disease of the skeleton. Heredity plays an unimportant rôle in the production of dwarfs, since usually the parents are of normal size, and, further, frequently dwarfs during early infancy do not differ from other children of similar age, the diminutive size, which later renders them conspicuous, attracting attention only as age advances. The history of the celebrated dwarf, Gen. Tom Thumb, is an interesting case in point. At birth he weighed rather above the average, but ceased growing when about five months old and less than twenty-one inches in height. He lived until nearly sixty years of age, having had one child by his dwarf wife, Lavinia Warren. "Princess Paulina," described by Nagel,[21] measured nineteen inches in height at nineteen years of age, when she died. She was perfectly developed in every way, and very intelligent, speaking four languages. At birth she measured twelve inches.

Among the instances of full-term children of exceptional smallness may be cited the case, noted by Home,[22] of a living child which weighed one pound and measured less than eight inches in length. At the age of nine years, when it died, the child had attained a height of twenty-two inches. Mursick[23] mentions a living infant weighing one and three-quarter pounds at birth; Baker[24] another of the same weight and fourteen inches long when fifty days old. In 1871, at Kalamazoo, Mich., occurred the birth of twins, a boy and a girl, weighing one and a half and one and three-quarters pounds respectively, their combined weight reaching three and one-quarter pounds. They were perfectly formed and, while less than eight inches, unusually active. Another case of diminutive twins, both girls, twenty-two and one-half and twenty-four ounces in weight, is interesting from the fact that both lived to adolescence.

Abnormalities of Position.—Congenital deviations from the normal position present differing degrees of displacement, varying from involvement of a single organ, as a depressed kidney or an undescended testicle, to the complete transposition of all the thoracic and abdominal viscera, as sometimes seen in marked examples of *situs inversus viscerum*.

Fig. 4645. Complete Transposition of Viscera. (Rüdinger.)

Since variations extensively involving the primary embryonic mass alone claim attention at this place, consideration of the minor deviations of position exhibited by organs, as well as the malpositions affecting the extremities, will be deferred until the description of the malformations of special parts.

Transposition of the organs (*situs transversus, inversio viscerum*) may be so complete that even the slight asymmetries which are usually observed on the two sides are all repeated, in reversed order, in the new arrangement, the functions of the organs remaining unimpaired. Complete situs transversus has been noted in about two hundred subjects, the two sexes being about equally represented. The case reported by Caton[25] presents a typical picture of this condition. The brain was normal, but the convolutions of the right Rolandic area were remarkably complex on the right side, the subject having been left-handed. The superior longitudinal sinus joined the left lateral sinus. The apex of the heart lay about four inches to the right of the mid line and a right aortic arch passed back to the right of the vertebral column and continued downward in that relation to the spine. A left innominate artery, right common carotid and subclavian sprang from the aortic arch. The left lung consisted of three lobes, the right of two, and the bronchi were transposed, the right passing beneath the aortic arch. The liver lay on the left, the stomach protruding to the right, while the spleen enjoyed its usual but reversed relations on the right. The duodenum, pancreas, cæcum, sigmoid flexure, and rectum were all transposed. The left kidney was lower than the right and the right testicle lower than the left.

The explanation of the production of situs transversus shares the uncertainty of our knowledge concerning the cause of the asymmetry which normally affects the heart and great blood-vessels and other organs. The early primitive heart, as is well known, after fusion of the two isolated primary heart tubes, for a short period occupies a median position as a straight canal which receives the vitelline veins at its caudal end and gives off the truncus arteriosus from its cephalic extremity. Very soon, however, marked flexion toward the right takes place and inaugurates the conspicuous asymmetry which henceforth distinguishes the heart and later involves the large arterial trunks.

In seeking an explanation of the constant flexion of the growing heart tube toward the right, the facts presented by the development of the chick are very suggestive. The earliest deflection of the heart takes place while the embryo lies extended upon the vitelline sac and before the torsion of the head toward the left has occurred; the primary cause of the cardiac expansion toward the right, therefore, cannot be referred to the twisting of the head and the application of its left side to the yolk sac. On the contrary, it is probable that the tendency of the rapidly increasing head to seek support for its broad lateral surface on the left side rather than the right is influenced by the development of the heart. The preponderance of the left vitelline, or omphalo-mesenteric vein, which normally is larger than the right in consequence of the greater development of the corresponding half of the vasculosa, has been regarded by Dareste and by Martinotti as the primary factor in causing the deflection of the heart tube in the opposite direction. Indeed, no one can carefully study the relations and evident impression of the left vitelline vein to the early heart in the chick embryo without recognizing the direct influence of this vessel in producing the right-sided expansion of the heart loop. The subsequent suppression of the right vitelline vein still further aids the early influences of the larger left vessel. It is not improbable that similar influences affect the development of the mammalian heart, although the inequality of the vitelline vessels, as shown by van Beneden in the rabbit, is conspicuous in the secondary changes which lead to the preponderance of the left vitelline artery.

The commonly accepted view that deflection of the primary heart toward the left is the initial morphological factor in producing transposition of the viscera finds support in the observations of Kölliker, Dareste, and others, as well as in the experiments of Fol and Warynski. These investigators likewise show that the reversed position of the early heart is associated with reversed torsion of the cephalic segment, so that the embryo rests with the right side of its head upon the yolk. While we may accept, therefore, unusual size and persistence of the right vitelline vein, associated with a corresponding diminution and suppression of the left, as the immediate cause of a reversed torsion of the heart tube and the subsequent situs inversus, we are compelled to recognize further influences to account for the fact that the abdominal viscera may be transposed, although the thoracic organs retain their normal position.

In seeking an explanation of such conditions, an examination of the causes leading to the normal asymmetry of the abdominal viscera will furnish suggestive facts. Kölliker, and especially His, have shown that the changes affecting the umbilical and the vitelline veins have much to do in determining the relations of the liver and the stomach. In the early embryo, the vitelline veins return the blood from the vascular area and, as a common trunk, open into the primary auricular extremity of the heart. After the establishment of the allantoic circulation, the two umbilical veins course in the lateral belly walls, passing beneath the diaphragm and over the primary liver anlage, to empty into the *sinus reuniens*, a transversely placed venous channel, which receives all the principal venous trunks—the vitelline, the umbilical, and the ducts of Cuvier. After a time the connection of the umbilical veins with the sinus renniens is broken when the formation of a vascular network within the rapidly growing liver takes place. The right umbilical vein, always less well developed than the left, subsequently largely undergoes atrophy, while the left umbilical vein increases and becomes the channel for the blood returned from the now rapidly augmenting placental circulation. The vitelline veins, which ascend at first in front of the intestinal canal and, higher up, lie on either side of the duodenum and the stomach, form transverse communications which thus enclose the duodenum within two vascular rings. The latter undergo partial atrophy in such manner that the right half of the lower and the left half of the upper annulus disappear, the remaining parts forming the upper part of the portal vein. The primary relations of the persistent portions of the venous rings to the primitive gut tube are preserved in the spiral course of the portal vein around the duodenum; the stomach lies to the left of the portal vein.

Since, in general, the usual situation of the liver and stomach are influenced by the persistence of the left venous trunks, the effect of the exceptional retention of these stems on the right side offers an intelligent explanation of the conditions producing transposition of these organs, the relation between a transposed stomach and a reversed portal vein being particularly intimate. Lochte[26] has emphasized, and we believe rightly, the responsibility of the omphalo-mesenteric and the umbilical veins in the production of transposition of the abdominal viscera, in this manner accounting for the reversed position of these organs when associated with normally disposed thoracic contents.

While the heart tube is extremely sensitive to influences inducing transposition, the impression of the vitelline veins on this organ is exerted only so long as these vessels have a direct communication through the sinus reuniens with the primitive heart. After these veins suffer interruption by breaking up into capillary networks within the primary liver, their influence no longer directly affects the heart, but, in conjunction with that of the umbilical veins, is expended upon the abdominal organs, which may be regarded, in a measure, as having an independent development. Since the modifications of the veins occur relatively late, and after the definite relations of the heart are established, the transposition of the abdominal organs may take place subsequently to the normal development of the heart and other thoracic viscera. Regarding the primary cause, which results in the persistence of the right venous trunks of the embryonic area, nothing is known. The very common, but not invariable (Koller[27]) transposition of the viscera observed in the right member of monomphalic double monsters is referable, according to Lochte, to the reversed relations which the right fœtus bears to the umbilical vein.

Duplicities.

The conspicuous malformations embraced in this group have attracted the study and the speculation of the most competent observers from the days of the Greek philosophers to the present, and even to-day, notwithstanding the advances in our knowledge of the primary phases of development, no problem of teratology calls forth more divergent opinions than the production of double monsters.

The salient peculiarities of these malformations readily suggested an origin by union, Aristotle holding that double monsters in viviparous animals were due to fusion of two yolks. Such views held sway for many centuries as the generally accepted doctrine, until the bitter discussions of ovists and animalculists, regarding the relative importance of the ovum and the spermatozoa, were extended to the production of duplicities by the rival schools. Lemery, in 1724, first advanced the opinion that double monsters resulted from the union of two embryos within the uterus—a theory, however, that met many opponents, among whom were Haller and Wolff. The objections of the latter were based upon his insight into the normal processes of development which his observations had taught him were incompatible with the assumption of a fusion of embryos already well advanced in their formation. Wolff pictured the possibility of a double monster arising within an originally single anlage* as the result of divergent growth due to "surplus vegetation."

During the first half of the nineteenth century the writings of the foremost authorities, among whom were I. F. Meckel, Johann Müller, Geoffroy St. Hilaire, Gurlt, Otto, Bischoff, and others, indicate an abandonment of the older conception of fusion as the union of two ova or of well-advanced embryos and the acceptance of the doctrine of fusion in a modified sense, it being recognized that the union must take place at a very early stage. Meckel, however, dissented from the generally accepted explanation of double monsters, as the result of the union of embryonic areas primarily distinct, and held, on the contrary, that such malformations might be produced by the excessive growth of the component halves of a single embryo due to unusual formative energy. Meckel thus appears to have first suggested the theory of fission, which subsequently had, and still has, many enthusiastic supporters.

The later writers who have busied themselves with the discussion of the production of double monsters constitute two schools: the one regarding the duplicity as the result of the union of two primary anlages in a single ovum; the other, as the result of a cleavage of a single anlage. Among the supporters of the first view may be mentioned Panum, Foerster, Dareste, Rauber, Gerlach, Marchand, Ziegler, and others, while the "fission" theory has been defended by Dönitz, Dittmer, Oellacher, Ahlfeld, and not a few later followers.

In considering the merits of these opposed views concerning the production of double monsters, it may be accepted as a fundamental principle that the initial changes leading to duplicity occur during the very earliest stages of development, an assumption of either fusion or cleavage of advanced embryos being untenable. The present conception of *fusion* recognizes the presence of two originally distinct anlages within a single ovum; these may remain separate and develop independently, leading to the formation of twins, or they may come in contact during growth and undergo more or less extensive union, thereby producing some variety of double monster. The fact that in such unions fusion occurs always between parts which are identical in character, as skull with skull, or liver with liver, although not necessarily at points identical in situation, has been advanced as an argument of weight against the acceptance of the fusion theory. It must be remembered, however, that equally remarkable exhibitions of selective affinity (*Loi d'affinité de soi pour soi* of St. Hilaire) are displayed during the normal processes of development, in the approximation and fusion which the somatopleura, splanchnopleura, and other originally separate parts undergo in the evolution of the body walls, the gut tube and organs developed from symmetrical halves.

* The writer adopts the convenient German word, "Anlage," as indicating the primary formative area of an organ, or of the embryo, as more satisfactory than any of the numerous English synonyms that have been suggested.

The explanation of the union of similar parts in double monsters is to be found in the extremely early age at which junction is effected and the inherent attraction of the subsequently produced differentiating tissues for their own kind, muscle seeking muscle, connective tissue joining connective tissue, and epithelium fusing with epithelium. The experiments of Born,[27] in which he succeeded in grafting portions of one amphibian larva upon another, afford many suggestive facts bearing upon the malformations under consideration. Examination of the artificially produced composite larvæ showed that in consequence of the tissue affinity, like organs became united by the fusion of their specific components; thus, the spinal cord of the anterior segment of one larva joined the like structure of the posterior part of a second; the sectioned immature digestive tubes united into a common canal, the Wolffian ducts sought each other, while among the simpler fusions were liver with liver, cartilage with cartilage, cutis with cutis, and epidermis with epidermis. Gemmill[29] confirms the law of union of homologous structures and points out that the primitive embryonic axis, the notochord, is tardier in uniting than either the neural or the digestive tube. It is to be noted that such direct unions are possible only in the early formative condition of the tissues; when once matured, union is effected only by means of comparatively elaborate reparative processes.

The *fission theory*, as presented by its most enthusiastic supporter, Ahlfeld, regards the duplicity as the result of cleavage of a single anlage during the very earliest stages of development, before the formation of the primitive streak. The earlier the cleavage, the more complete the division of the anlage, or, conversely, the longer deferred, the more incomplete the fission. The cleavage force is probably expended earliest and most forcibly upon the cephalic pole of the anlage, from which it follows that partial division of the upper half of the body is so commonly encountered. According to Ahlfeld, the immediate agency in producing the cleavage is to be sought in the mechanical resistance offered by the zona pellucida in consequence of an abnormal increase of the formative material. Since the greatest force exerted by the zona pellucida will be expended on the most prominent part of the embryonal mass, later the cephalic portion of the embryo, the early and profound cleavage affects this segment. Ahlfeld's conception of the results of cleavage so induced includes an associated secondary rotation and divergence of the separated segments of the anlage in proportion to the extent of the fission. If the cleavage be complete and the pressure of the zona pellucida be exerted equally on all portions, the segments will separate but remain parallel; if the cleavage be incomplete, and, therefore, the anlage be still undivided throughout part of its extent, the separated portions will bend in opposite directions, or diverge, thus producing anterior or posterior duplicity. In case the cleavage is complete, with the exception of a limited undivided portion at either cephalic or caudal pole, the segments may diverge and rotate until their axes form a straight line, as in the conspicuous examples of craniopagus, where head is attached to head and the body axes coincide.

The ingenious theory advanced by Ahlfeld, as sketched above, in support of the fission doctrine does not stand the test of embryological criticism, since, as pointed out by Gerlach and emphasized by Marchand, the assumption, that the early embryonic anlage, constituting a part of the delicate and yielding blastodermic vesicle, can be influenced by the attenuated zona pellucida to the extent of inducing a mechanical cleavage, is not in accord with the facts of development.

Although neither the theoretical views of Ahlfeld concerning the production of double monsters, nor the universal application of fission in explaining all forms of duplicity accorded by this author, can be accepted without challenge, yet it must be admitted that certain types of anterior incomplete duplicity are accounted for more satisfactorily by an assumption of cleavage of the anterior end of a primarily single anlage than by fusion.

Were two separate anlages to unite to an extent necessary to produce an anterior doubling of the form shown in Fig. 4655, it is difficult to admit that the anterior ends of the primary embryonic areas would fail to become likewise blended during the development of the prominent cephalic segments. We are compelled, therefore, to seek an explanation of anterior incomplete duplication in some process resulting in the doubling of the early head end to a greater or less degree.

Gerlach, who presents in his admirable monograph[30] a critical analysis of the various theories regarding the production of double monsters, suggests a modification of the usual conception of fission which has much to recommend it. According to the later views of this author,[31] incomplete anterior duplication results not in consequence of a fission of the anterior end of the anlage, but is the result of "bifurcation" accompanying the development of the cephalic end of the young embryo along diverging axes. Bifurcation in this sense fundamentally differs from fission, since the former is the product of active formative processes, the latter the passive result of mechanical forces. Whether the duplication and divergence of the axes are the direct result of mechanical influences, as held by Klaussner,[32] or whether bifurcation occurs independently of such forces, as assumed by Marchand,[33] it is certain that the impression inducing the division affects the anlage at an early stage, and that the degree of duplication is directly proportionate to the time at which the influence was exerted—the earlier its action the more profound the impression and the more extensive the anterior duplication. Examples of comparatively late impressions are seen in the slight duplicity involving limited parts of the head.

The suggestive facts contributed by the results of the interesting investigations in experimental embryology by O. Hertwig, Roux, O. Schultze, Driesch, Wilson, Morgan, and others, are of importance in adding to our understanding of the fundamental principles of both normal and abnormal development. These investigations have shown that in the segmenting ova of amphibian and lower forms the first cleavage virtually establishes a differentiation into right and left body halves, since under normal conditions from each of the two segmentation cells, or blastomeres, a half embryo arises. Under modified conditions, however, each blastomere is capable of producing an entire perfect, although undersized, embryo. The conditions necessary to secure the latter result seem to be such that bring about a readjustment of the egg materials contained within the blastomere to correspond, in a sense, in arrangement and equilibrium to the entire ovum. Morgan[34] discovered that according to the position of the blastomere half-embryos, or whole dwarf embryos, could be produced at will. If, after destruction of one blastomere of the two-celled stage, the other be retained in its normal position, a half-embryo resulted; if, on the other hand, the blastomere be inverted, either a half-embryo or a whole dwarf was produced. These observations are in accord with the discoveries of O. Schultze,[35] who found that by fixing a frog's ova in an inverted position for about twenty hours he obtained, with remarkable regularity, double malformations instead of the usual simple embryos. It is of interest to note that the experiment was successful only when the eggs were inverted as soon as the first cleavage had been completed; double monsters were never produced when the misplacement was effected before or after this stage. The resulting malformations presented various arrangements in the relation of their axes; sometimes one blastomere developed into a complete dwarf, while the other produced only the anterior segment. In some cases the dwarf embryos were united along their ventral surfaces, or back to back; in others a common trunk terminated in two distinct diverging heads; exceptionally, the cephalic segments were directed in opposite directions.

These experiments point to the important conclusion that each of the two primary blastomeres contains the materials necessary to produce an entire body, although under usual conditions of development each contributes but half. O. Hertwig[36] has recently expressed his belief that duplicity is associated with the occurrence of double gastrulation, such variation resulting in the production of the double malformations conspicuously seen in the lower vertebrates. He also regards the duplicities among the amniota as referable to a modification of the same process.

Etiology.—The complete or partial symmetrical duplicity, whether produced immediately by fusion or cleavage, is evidently the result of primary disturbances or unusual conditions affecting the primitive germ mass. The determination of the initial causes which bring about double malformations has been, and still is, one of the most difficult and vexed of teratological problems toward the solution of which little more than speculation can be offered with our present imperfect knowledge.

A. The assumption of inherent peculiarities within the unfertilized ovum, while perhaps of much importance for the current theories concerning the causes leading to the production of double monsters, is speculative and incapable of direct demonstration by the means at the disposal of the biologist.

Suggestive facts, pointing to the possibility that at times the peculiarities of the ovum may be responsible for the production of double monsters, are afforded by the observations of Rauber and of Born. These experimenters showed that the eggs of certain individual fishes were conspicuous by reason of the frequency and repeated occurrence of double malformations arising from their development. It cannot be assumed, however, that the existence of such predisposition can be discovered in any recognizable morphological peculiarity in the ova.

The presence of more than one nucleus, or germinal vesicle, within the ovum has long been regarded as a condition favoring the production of double malformations. The observations of Féré[37] on the hen's eggs show that while in certain cases the development of such ova leads to the formation of two distinct embryos, in others fusion of the early embryonal areas takes place and duplicity results. Wetzel[38] describes interesting examples of multiple areas originating in snake eggs, and regards the evidence convincing in establishing such origin for certain types of duplicity. In addition to the many instances encountered in the eggs of birds and of the lower forms, a number of observers, Franque, Stöckel, Rabl, and Schumacher and Schwarz, have noted human ova containing more than a single nucleus. The last-named authors[39] regard such eggs as capable of giving rise to duplicities. Blanc[40] agrees with Dareste in holding that all double forms originate from ova with two nuclei. O. Schultze,[41] while less radical, regards the presence of two nuclei as one of three possible sources of double malformations.

The most serious obstacle in accepting such origin of duplicities is the difficulty of explaining satisfactorily the fertilization of the double ova. According to our present conceptions relating to the higher animals, fertilization implies the addition to the egg of a definite number of paternal chromosomes and a centrosome through the entrance of the spermatic filament and the formation of the sperm-nucleus. Since the quota supplied by a single spermatozoon is sufficient to unite with only a single egg-nucleus, it follows that no provision is made for the fertilization of the second germ. The assumption, frequently accepted, that fecundation in these cases is accomplished by the entrance of more than a single spermatic element—polyspermia—seems very doubtful when applied to the human species, since it is probable that this never takes place so long as the ovum is healthy and capable of developing. Sobotta,[42] one of the most recent writers who has reviewed the merits of the double-nuclei theory, rejects the latter as insufficient to account for double monsters. Broman,[43] in meeting these objections to the foregoing theory, holds that certain double-tailed forms of spermatozoa (more fully described under the next heading) are capable of fertilizing the two nuclei, since by this means two centrosomes,

Teratology.

as well as a double quota of paternal chromosomes, are introduced into the egg.

B. Peculiarities of the male sexual cell, when assumed as inherent predisposing influences, are as much a matter of speculation in relation to the production of double monsters as are similar causes attributed to the ovum. The aberrant forms of spermatozoa, described by many observers and regarded by some [44] as physiological, have been considered as directly connected with the production of duplicity, being looked upon as homologous with the ova with two germinal vesicles. Retzius,[45] however, inclines to the view that doubling of the tail results from separation of the two filaments, which, probably, normally constitute the axial filament. Broman has exhaustively studied these atypical forms and divides them into:

(*a*) Spermatozoa presenting deviations in size—giant and dwarf cells.

(*b*) Spermatozoa with a single head, but with two or more tails.

(*c*) Spermatozoa with two or more heads with one or more tails.

(*d*) Spermatozoa deviating from the normal in the form.

Of these, the variations included within groups (*a*) and (*b*) are those accredited as being most closely related to the production of double monsters as assumed by Ballowitz [46] and Broman. The latter excludes the influence of the double-headed forms since their morphological peculiarities impede progress to such extent that the handicap precludes victory in the race toward the ovum with the normal competitors. The double-tailed spermatozoa, on the other hand, possess an advantage both in their more efficient propelling apparatus and in the double centrosomes which the filaments convey. Broman regards the double-tailed forms as important factors in producing duplicities, not only since they may possibly lead to fertilization of ova with double nuclei, but also since, according to this author, they may supply the impulse resulting in the later subdivision of the segmentation mass into two germ centres.

Abnormal segmentation, as an assumed distinct cause of duplicity, is closely related to the foregoing group, since polyspermia is regarded as a potent factor leading to such variation. The considerations weighing against the latter assumption, as applied to the higher animals, are, as already noted, the improbability that more than one spermatozoon gains entrance to a normal ovum and the probable inability of an ovum so invaded to undergo development, since the lessened resistance implies diminished vitality.

Although abnormalities of segmentation *per se* cannot be regarded as playing an essential rôle in producing double malformations, the nearly related condition, in which more than a single formation centre is established, must be regarded as the most important immediate forestep of duplicity.

The difference between the results of the development of the separated first or second pair of segmentation cells and of the subdivided germ mass originating from the normal cleavage of the ovum must be distinguished. The first conditions would probably give rise to two entirely distinct individuals; under the second would follow the production of two closely related germinal areas capable of undergoing fusion.

The most important influences leading to double monsters are, therefore, those that are expended upon the segmented ovum during its early differentiation and result in the establishment of two centres from which development proceeds. Windle [47] regards such condition as dependent upon superfluity of germ-plasm attributable to faulty extrusion of the polar bodies following the entrance of double-headed or atypical spermatozoa [48] or of polyspermia. The latter is also accepted by Duval [49] as the chief cause of the redundant development. Laguesse and Bué,[50] incidental to the description of an early anterior duplicity of only 19 mm. length (probably the smallest human double monster ever recorded), follow Duval in assigning to polyspermia an important rôle.

Although little more than speculation, the most plausible view concerning the origin of the two formative centres, in the light of the more recent experimental studies upon segmentation, attributes the division of the blastula to influences which impress the ovum before their effects are manifested in the appearance of the two germs. That these influences may at times be external is suggested by the experiments of Schultze, Wetzel, Wilson, Loeb, and others with the eggs of the lower forms under modifying conditions. Regarding, however, the development of the higher animals, the assumption of influences dependent upon internal causes seems more plausible. That such may be paternal, as well as maternal, is supported by direct observation. The period at which the deviation from the normal development first becomes definite probably varies, in some instances closely following the early stages of segmentation, in others not until the blastodermic vesicle has been formed.

In connection with the production of true parasitic duplicities, distinguished by great primary inequality of the two anlages, the possible importance of a polar body as the origin of the parasite has been suggested. In our present knowledge, the polar bodies must be regarded as ova of greatly reduced size, but capable of being fertilized (Sobotta [51]). The development of such cells into an imperfect blastula, and later parasite, has been assumed by Marchand [52] as a plausible explanation of the origin of the lesser embryo. These true parasitic duplicities must be distinguished from those in which the disparity between the germs is due to differences in growth and nutrition of what originally were equal anlages.

Classification of Duplicities.—Any adequate grouping of double forms must take into account the developmental as well as the morphological characteristics of the malformations, hence the classifications proposed by different teratologists from time to time have exhibited, more or less markedly, the impress of their views regarding the production of these abnormalities. Although the influence of the teachings of St. Hilaire, and especially of Foerster, is evident in the classifications suggested by later writers, the extent to which the theory of fission or of fusion is accepted as sufficient for the explanation of duplicities largely determines the classification adopted. That proposed by Ahlfeld represents a fission-grouping of the most pronounced type, while the elaborate classification advanced by Taruffi is based upon the opposite assumption of fusion.

In view of the probability, now admitted by many, that although some forms of duplicity are attributable to fission, in many others fusion occurs, a classification is desirable which shall take into account the possible variations in the mode of production. This necessity was recognized by Cleland, who, although accepting fission as the primary process, included in his grouping secondary unions. The division of duplicities adopted by Marchand, which includes the best features of the classifications of St. Hilaire and of Foerster, presents a happy compromise in accordance with recent opinion; this classification, therefore, forms the basis for the grouping here followed.

Duplicities fall into two chief divisions: those in which the two primary germ masses, or anlages, are originally *symmetrical*, and those in which, from the beginning, marked discrepancy exists; the latter are, therefore, *asymmetrical*.

Symmetrical Duplicities.—These may be either *complete* or *incomplete*, the former group including the double forms in which the bodies of the two embryos are entirely distinct, as in twins developed from a single ovum, the latter group embracing the double forms which present more or less extensive union, as exhibited in the various types of double monsters.

Twins developed from a single ovum are distinguished from those originating from different eggs by the possession of a common chorion, although an amnion and an umbilical vesicle are usually formed for each; such twins are said to be *monochorionic*. They are further distinguished by remarkable similarity in their physical, as well as mental, characteristics, being always of the same sex, complexion, and feature. In recognition of these close resemblances, and of their assumed origin by complete fission of the original anlage, Ahlfeld applied the name, "homologous twins" to these duplicities. The only suggestion of union presented by such fœtuses is the single placenta which serves as the common source of nutrition. The conditions of nutrition and the rate of growth of one-egg twins may be so similar in both individuals that their development is *equal*. In exceptional cases the one may exactly correspond with the other in length and weight, as shown by the careful observations of Schatz.[58] More commonly, however, the development of such twins is *unequal*, as evidenced in the more or less marked discrepancy in their size and weight. If the difference is slight, the less favored individual suffers only to an unimportant degree and after birth is fully able to maintain an independent existence. If, on the other hand, the nutrition of one fœtus becomes seriously impaired, its death may occur and its body be subjected to pressure by the increasing bulk of the more fortunate companion. When such conditions arise during the earlier months of pregnancy, the dead product of conception is pushed against the wall of the enveloping sac and later the uterus, and subjected to gradual compression, which results in flattening and distortion to such extent that it is known as *fœtus papyraceus*.

The intimate relations between the placental circulations of monochorionic twins include not only a common placental area containing anastomoses of the capillaries of the chorionic villi, but also, with few exceptions, a superficial anastomosis between the smaller twigs of the umbilical vessels.

The most constant and important of these direct communications between the circulatory systems of the twins is that formed by the capillaries within certain villi to which the blood is supplied by vessels from one fœtus and carried away by those from the other. These areas of *capillary transfusion* usually occur along the blending line of the two placentæ and are designated by Schatz as the *third placental circulation*. This author concludes from his careful observations that the most common type of placental anastomosis is where, in addition to the constant communication existing within certain villi, a single, seldom double, *arterial* anastomosis is formed between the superficial vessels. The next most frequent type is distinguished by a single, rarely double, superficial anastomosis of both the *arteries* and the *veins*. The additional possible relations of the superficial vessels, *venous* union and *absence* of anastomosis, are comparatively rare.

In consequence of the communications within the villi common to both circulations, it follows that in some villi the blood supplied by one fœtus, A, passes into the vessels of the other, B, and, conversely, blood contributed by B enters the circulation of A. The transfusion is, therefore, opposed. Although an accurate balance of these contrary blood streams is supposable, in fact a greater or less discrepancy exists with few exceptions. In many cases this difference is compensated by the superficial anastomosis, but in others this means does not suffice, and the adjustment of the dynamic asymmetry must be attempted by functional changes within the fœtuses. The necessity thus established may be productive of only inconsequent alterations; on the other hand, when associated with obstruction of the blood current within the umbilical vein of one twin, it may result in profound and even disastrous change.

Unequal Monochorionic Twins.—Since equal growth of one egg twins implies an equal apportionment of the placental area, any condition that materially disturbs the nutritive balance tends to affect adversely the less favored fœtus. Among the early sequelæ of such disturbances are the impaired, or even arrested, growth of the heart and the appearance of symptoms resulting from the stasis induced by obstruction of the blood stream within the weaker fœtus, expressed by the hepatic congestion and subsequent atrophy, œdema, and ascites.

When impairment of the circulation of the weaker fœtus occurs at an early period, the heart may suffer to such extent that not only is its development arrested, but atrophy and even disappearance of the organ may follow, thereby contributing to the malformation known as *acardius*. The loss by the affected fœtus of its capability of maintaining an independent nutrition is compensated, to a greater or less degree, by the stronger twin, which, by means of inosculations established between its placental vessels and those of the impaired fœtus, assumes the nutrition of its weaker mate. By virtue of such arrangement the blood current within the latter suffers reversal, usually a single umbilical artery conveying the blood to and a corresponding vein from the body of

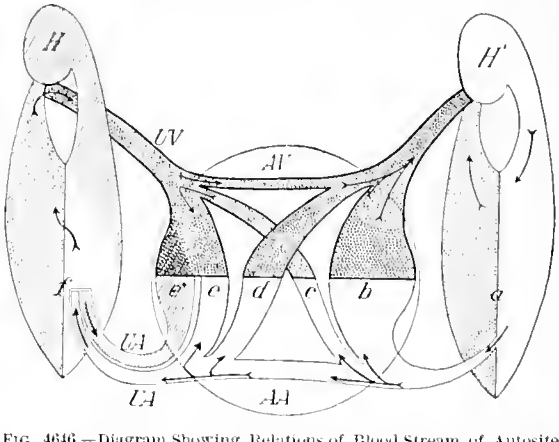

FIG. 4646.—Diagram Showing Relations of Blood Stream of Autosite and Parasite in Acardius. Circle indicates fused placental areas. Blood passes from autosite (*a*) by umbilical arteries to placenta (*b*); in addition to returning to heart of autosite (*H'*), part enters circulation of parasite by villous (*c*) and by arterial anastomoses (*AA*), following the paths indicated by arrows. The reversed current passes by umbilical artery into arteries of parasite, finding its way into the venous stems in consequence of obstruction and obliteration of heart (*H*) and associated large vessels, and returns to placenta by umbilical vein and thence by venous anastomoses (*AV*) into circulation of autosite. Unshaded areas represent arterial paths; light stipple, venous circulation of fœtus; dark stipple, venous paths; lined areas, obliterated tracts. (After Schatz.)

the dependent fœtus. Under such conditions of unequal development one twin becomes in a sense a parasite, since the continuance of its life may be entirely dependent upon the circulation of the other.

The period at which the fœtus becomes thus dependent exerts a profound influence upon the general development which it attains. Occurring early, before the organs and definite form of the fœtus are well established, the formation of such parts may be rudimentary or entirely suppressed. In consequence of the inadequacy of the donated circulation, which at best is only an imperfect substitution, it is usual to find acardius associated with conspicuous deficiencies of other parts of the body. The head particularly is imperfectly formed, often bearing little resemblance to the normal part. When partially developed, the condition is known as *paracephalus*, in which the brain is very rudimentary or entirely wanting, the eyes are imperfect or absent, and the face is malformed. Total absence of the head constitutes *acephalus*. These deformities of the head are usually associated with malformations of the trunk and limbs, the former being abnormally small, contracted, or misshapen, the latter defective or partially suppressed. The upper extremities are particularly prone to suffer, not infrequently being entirely wanting, although the lower limbs, by reason of their more favorable relations to the nutritive vessels, may be fairly well developed. In rare cases even these suffer, so that only a rudimentary single inferior extremity is present.

The internal organs, especially those closely related to the vascular system, are profoundly affected. Thus, in addition to lack of development of the heart, the liver is usually wanting, and, further, the lungs are more or less rudimentary. Defective development of the digestive tube, the kidneys, and other abdominal organs often coexists.

When the arrest of development is of the highest degree, the body of the dependent twin becomes reduced to a misshapen mass presenting slight resemblance to the human form. Such monsters, which may be little else than irregular nodules invested with œdematous skin and attached by an umbilical cord, constitute the form termed *amorphus*.

Acardiac Monsters.—Reference has been made to the occurrence of acardiac monsters in consequence of impairment of the placental circulation of one of monochorionic twins. It will be desirable, therefore, to consider more fully the group of malformations in which partial or complete absence of the heart is often a conspicuous, but by no means essential, feature. The distinguishing characteristics of a true acardius include not only the impaired development of the heart, but also a circulation dependent upon a stronger fœtus and a *reversal of the blood current*.

The views regarding the production of acardius held during the middle and immediately succeeding decades of the last century by many teratologists, including H. Meckel, Dareste, and Panum, assumed primary defect or death of the heart as the essential factor in bringing about this condition, the cardiac imperfections, in the first place, being caused or accompanied by primary defects of the entire embryo.

Claudius, however, opposed this opinion and maintained that in placental anastomoses lay the chief factor, since, according to this author, the arteries of the two fœtuses united and thus brought the two blood streams into direct opposition. Assuming that the heart of one twin acted less vigorously than that of its mate, Claudius held that the blood current propelled by the stronger heart overcame the circulation of the weaker and reversal of the blood stream within the latter followed. In consequence of this change in the direction of the blood current, Claudius assumed that the heart of the weaker fœtus becomes embarrassed and impaired, and is brought to a standstill, followed by atrophy and final disappearance. Absence of heart was regarded, therefore, by this author as a constant condition of all forms of acardius.

The particular service of Claudius was to emphasize the important fact, originally observed by Hempel, of the reversal of the blood stream and to contradict the assumption of an inherent defect of the heart as necessary for the production of acardius. The effects attributed by Claudius to the arterial anastomoses and the supposed struggle for supremacy between the blood currents are less happy, since, as pointed out by Schatz, the assumed opposition does not exist, for instead of being driven against the stream propelled by the heart along the umbilical arteries, the blood entering the circulation of one fœtus from that of the other must pass in the direction of least resistance. This being toward the placenta, and not toward the heart, the transferred blood will join that already journeying along the umbilical arteries to the placenta, and within the latter pass into the returning veins, and so on to the heart to the nutrition of which it will contribute instead of impair. Ahlfeld has championed the views advanced by Claudius and attempted by new assumptions to strengthen their defective arguments. Thus, this author regards the capillaries of the placental villi as the seat of the reversal of the blood stream, and suggests that from the beginning the acardius may be regarded as an "allantoic parasite" in consequence of the tardiness with which it forms its placental attachments. According to Ahlfeld, during this late development, the allantois of the weaker fœtus grows into that of the stronger, in the course of which process anastomoses become established between the two circulations; as a result, that of the less vigorous twin is overpowered by the blood stream propelled by the stronger heart.

Although recognizing, as all now must, that the explanation advanced by Ahlfeld is incompatible with our present knowledge concerning the formation of the early attachment of the human embryo to the serosa by means of the belly stalk and the absence of a free allantoic vesicle, Marchand inclines toward a modified acceptance of somewhat similar views. This authority assumes a primary inequality of the two embryonic anlages with a corresponding discrepancy in the development of the mesoderm, belly stalk, amnion, and umbilical vesicle of the two embryos. In consequence of this unequal growth, asymmetry results by which the smaller fœtus becomes united by its belly stalk to that of the larger in such manner that they represent a form analogous to double monsters with posterior union and diverging axes. The anastomoses between the blood-vessels of the dissimilar placental areas furnishes the path through which the circulation of the weaker fœtus is overpowered and replaced by the extension of blood stream of the stronger. The defect of the above theory lies in its inapplicability to the explanation of the important group of hemiacardii in which the changes may appear so late in intra-uterine life that the heart and other organs closely associated with the development of the circulation are affected to only a relatively slight degree.

It is to the careful investigations of Schatz that we are indebted for a comprehensive view of the acardii and the related forms of malformation. The conclusions of this author form the basis of the opinions here expressed. Before entering upon a consideration of their production, it will be of advantage clearly to appreciate the groups into which these malformations fall. They are: *holoacardius*, in which the circulation is derived *entirely* from the stronger twin, irrespective of the presence of a more or less perfect heart in the affected fœtus; *hemiacardius*, in which only a part of the fœtus is supplied by the stronger heart, the remainder being nourished from the circulation of the affected fœtus. It is sufficient for the production of a hemiacardius that the reversed blood current is limited to one umbilical artery and only a lower extremity is supplied by donated blood. On the other hand, the entire body of the hemiacardius, with the exception of a small part, may be nourished by the reversed blood stream. Schatz recognizes an additional group of analogous malformations, *pseudoacardii*, in which reversal of the circulation never occurs and placental anastomoses are wanting. *Microcardius* and *macrocardius* are conditions of under- and over-weight of the heart depending upon the variations of nutrition associated with modifications of the placental circulation of monochorionic twins.

Reversal of the circulation, therefore, is the one condition constant in all forms of true acardius, complete or partial alike. Absence of the heart is not, since in hemiacardius developed at a late period this organ may be present and even functionating; conversely, single, unassociated embryos sometimes possess hearts no more perfectly developed than those of recognized acardii.

The periods at which acardii may originate are:

1. *Before the heart has developed.* The heart is formed, as well known, by the fusion of two heart-tubes which are developed independently of the vessels of the vascular area, the latter vessels subsequently growing toward the embryonic axis and joining the primitive heart. When, for any reason, the development of this organ is arrested and the vascular areas of the two embryos lie in close relation, the vitelline circulation of the impaired embryo may form anastomoses with that of the normal twin so that the latter assumes, as far as possible, the nourishment of both embryos. Under such conditions, the embryo, which if unaided would necessarily die, continues its development and becomes a parasitic acardius.

2. *After the heart has developed*, but before the establishment of the allantoic or placental circulation. In case heart-death occurs, either primary or secondary, at a time when the vitelline circulation is still formative, anastomoses may still occur in sufficient number to provide succor for the imperilled embryo, which under such conditions may become a parasitic acardius. Since the

development of the allantoic circulation does not take place under such circumstances, a placenta and cord are not formed.

3. *After the establishment of the allantoic or placental circulation.* This period produces the forms usually included as acardii in the origin of which defects of the placental circulation play an important rôle. Mention has already been made of the fact established by Schatz, that the placental circulations of monochorionic twins are united by two forms of anastomoses—the constant communication effected by the chorionic villi common to the vessels of both fœtuses and the more variable communication effected by the superficial anastomoses, at times limited to the umbilical arteries, at others involving both artery and vein, less frequently only the umbilical vein.

In exceptional cases, which may, however, occur at any time between the completion of the placental circulation and the middle of gestation, acardius may arise in consequence of primary heart-death followed by transfusion of the blood within the umbilical arteries of the stronger fœtus into the corresponding vessels of the impaired twin in consequence of the diminished blood pressure within the latter. The blood thus contributed by the stronger fœtus flows both to the placenta and to the body of the weaker; should the nourishment be insufficient to maintain both placenta and body, the one or the other suffers unless the meagre supply is equally shared.

Although in these comparatively rare cases the placental anastomoses, following the primary heart-death, directly produce the acardius, such communications in themselves are incapable of originating these malformations, the reversal of the blood stream being dependent upon a cause to which the failure of the heart and the subsequent change in the direction of the circulation are secondary.

The investigations of Schatz render it highly probable that this primary cause lies in obstruction along the course of the umbilical vein, either within or without the body of the fœtus, at any point between the heart and the placenta. In consequence of the gradual narrowing of the vessel returning the blood from the placenta, the amount passing to the heart is correspondingly diminished until, sooner or later, this organ is more or less completely deprived of the supply necessary to maintain its nutrition and function. The result of this restriction is increasing impairment of the heart's strength and consequent diminution of the blood pressure within the umbilical arteries. When the resistance offered by the failing powers of the impoverished heart is reduced to a sufficient extent, the blood stream conveyed through the placental anastomosis from the stronger twin overcomes that within the weaker fœtus and reversal of the circulation within the latter gradually takes place. In consequence of this reversal the weaker heart, sooner or later, is brought to a standstill and an acardius results. The rapidity with which these changes are effected depends upon the rapidity and the extent with which the venous obstruction develops. Although the superficial placental anastomoses suffice to compensate for inequality in the transfusion taking place between the twins, such communications are powerless to neutralize the effects of the hindrance caused by stenosis of the umbilical vein. On the contrary, they aggravate the untoward transfusion inequality, since the superficial venous anastomosis offers a ready escape for the retarded blood current into the circulation of the unaffected fœtus, and the arterial anastomosis provides the channel by which the blood from the vigorous heart passes into the reversed circulation of the acardius.

After the establishment of the acardius, the obstruction within the umbilical vein may remain stationary, or after a time it may decrease, since the returning blood current, which now passes along the vein, is under higher pressure than before the assumption of the circulation by the stronger heart. In those cases in which the narrowing of the umbilical vein is permanent, at a time very shortly after the appearance of the budding limb, the meagre supply of blood suffices for the imperfect development of the embryo into the globular amorphus type of acardius, in which the retarded return of the blood from the fœtus results in œdema and failure of development of the internal viscera. When the obstruction appears relatively late, the deficient development may result in producing an œdematous acephalus instead of the more typical amorphus.

It may be emphasized that, in general, the acardii are formed from normal embryos, and, further, that the time of their production may be at any period of gestation, from the early relations of the embryonic areas resulting in the development of a parasitic acardius, on the one hand, to the conversion of a hemiacardius into an acardius near the close of pregnancy on the other.

Although at times the reversed blood stream and the impaired heart are the only defects, in other cases conspicuous malformations are associated with the acardia. These defects may be grouped as *primary* and *secondary*, the former including such as exist prior to the acardia, the latter after its appearance.

The primary defects, again, embrace those which are *intrinsic* and those which are *accidental*. Among the intrinsic primary defects may be mentioned irregularities in the development of the venous system associated with *situs transversus*, absence of the ductus venosus, faulty formation of the liver and its veins, or malformation and stenosis of the umbilical vein. The accidental primary defects are such as have no connection with the condition of acardia, as spina bifida.

Regarding the grouping and the fundamental circulatory conditions of the several types of acardiac monsters, the conclusions of Schatz may be followed with advantage.

I. *Acardii completi*, in which a fairly well-developed trunk and head are present, the limbs being represented by the full complement or by the members remaining after the suppression of one or both upper or lower extremities. The various degrees of development of the head are expressed by the terms *holo-*, *para-*, *oma-*, and *hemicephalic*. Since the different types of acardii depend for their production largely upon the amount and character of the blood supply derived from the stronger twin, it is of interest to consider the probable relations existing in the complete acardii. Bearing in mind the fact that, even under the most favorable conditions, the nutritive requirements of the dependent twin must always remain insufficient, it will be appreciated that in order to secure the degree of development sometimes seen in the complete acardii, the fœtus has enjoyed the most advantageous conditions possible under the circumstances. This implies an approximately sufficient nutrition by means of a well-balanced circulation, the blood stream entering by the umbilical arteries being carried away from the fœtus by venous channels of adequate capacity to insure the necessary blood pressure, and at the same time to prevent stasis. The general development of the acardius depends upon the sufficiency of the blood supply forced into its various parts by the active heart; the occasional instances in which the affected fœtus is relatively well-formed are possible because of the ample and direct anastomosis between the placental circulations.

II. *Acardii acormi*, which possess only the head, with possibly traces of the trunk and limbs, constitute a conspicuous group of monsters depending for their production upon the effects of unusual combinations in their venous channels.

The remarkable acormous acardius represented in Fig. 4647, carefully recorded by Barkow, may serve to illustrate the manner in which, as interpreted by Schatz, such rare malformations originate. The production of an acormus implies a close and intimate primary anastomosis between the vitelline circulation of the fused embryonic anlages. Although the communication between the two vitelline veins at first consists of numerous vessels, during the subsequent development of the embryos the inosculation is reduced to paths forming a single main channel, the *common vitelline vein*. Under usual conditions, this vessel becomes impervious and atrophies upon the establishment of the allantoic circulation. In response to the imperative necessities of impaired nutrition, however, it may remain and take an important part in the nourishment of the acardius.

In consequence of early obstructed circulation due to stenosis or arrest of development of the allantoic vein of

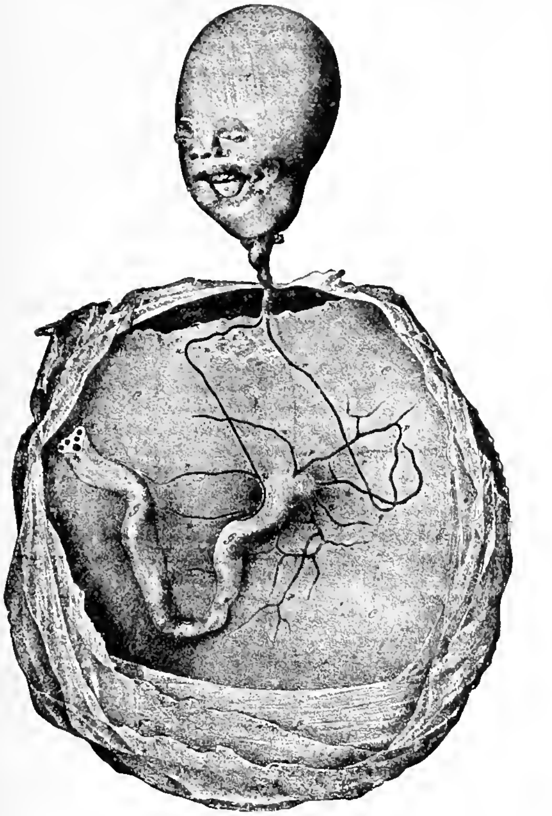

FIG. 4647.—Acardius Acormus. Rudiment of left upper extremity and of digestive tube. (Barkow.)

the subsequent acardiac fœtus, the blood pressure of the latter becomes lessened, followed by the passage of the blood from the systemic veins of the stronger twin into the weaker fœtus by way of the still present common vitelline vein. Notwithstanding the improved nutrition thus secured, the heart sooner or later becomes enfeebled in consequence of the inadequate blood supply and the greatly increased length of the circuit through which the blood passes. With the development of the umbilical cords, the common umbilical vein is included within both, and hence the blood which is carried to the placenta by the umbilical arteries of the future acardius must pass, in order to return to the latter, through the placental villous anastomoses into the umbilical vein of the normal fœtus and thence to the point of entrance of the common vitelline vein; then along the entire length of the umbilical cord back to and across the placenta, into and along the entire length of the cord of the second fœtus to the overburdened and under nourished heart—the blood being propelled by the latter through a course over three times the length of its normal circuit. In consequence of these demands, the insufficiently nourished heart gradually becomes more and more enfeebled, until a period arrives when the reduced blood pressure within the weaker fœtus is overcome by the circulation of the more fortunate twin, and the blood of the latter passes, by means of the superficial placental anastomosis, from the umbilical artery of the stronger into the corresponding vessel of the weaker twin. The reversal of its circulation so induced, following the heart-death, affects not only the blood current within the umbilical arteries, but also within the extended path formed by the common vitelline vein, the typical condition of acardia being now established. Since the vitelline vein affords a ready exit for the blood carried by the superior vena cava, the circulation supplying the cephalic end of the fœtus is comparatively well maintained, and hence the conspicuous development of the head and immediately succeeding part of the trunk, and the suppression of those portions of the body not in relation with the superior vena cava.

III. *Acardii acephali* form a group in which the lower or pelvic portion of the trunk constitutes the chief representative of the body of the malformed fœtus, to which other parts of the trunk, together with all, some, or none of the limbs, but no head, may be added.

In considering the anatomical factors active in the production of such headless forms, the importance of the collateral venous anastomoses, by which the obstruction in the umbilical vein is partially compensated, becomes evident. The most important collateral path, probably, is that afforded by the enlargement of the veins of Burow, small branches within the abdominal wall connecting the umbilical and deep epigastric veins. Since the most active circulation, and hence most efficient nutrition, is determined by the position of the channels affording the readiest return of the blood, those portions of the acardius affected by the blood current established by means of the collateral vessels will be most favorably

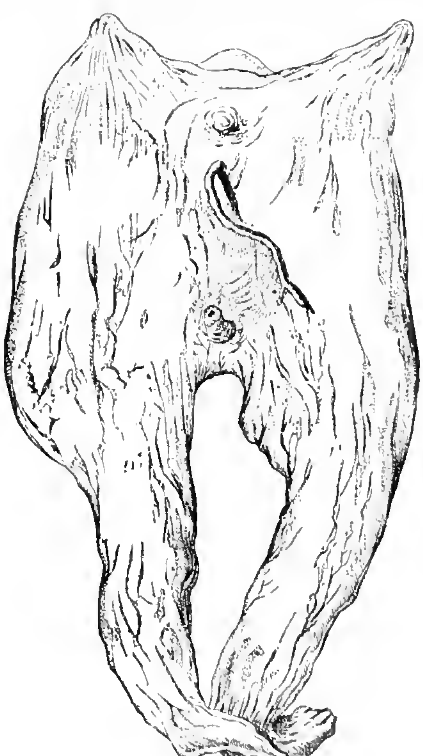

FIG. 4648.—Acardius Acephalus. (Herholdt.)

influenced. These parts will be evidently primarily the lower part of the trunk and the inferior extremities, which are preserved and undergo further development. At times additional veins within the body walls are included within the collateral circulation, the favorable influence of which is thus extended to a larger part of the trunk. The common vitelline vein not being available, either by reason of the late period at which the acardius was developed, or because the formation of the vein never took place on account of separation of the embryonic areas, the head remains unprovided with an active circulation, and hence fails to develop, the result being the production of the acephalic type of acardius.

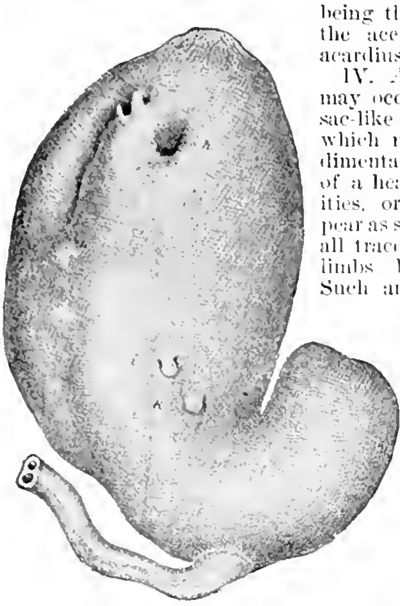

FIG. 4649.—Acardius Amorphus. (Barkow.)

IV. *Acardii amorphi* may occur as irregular sac-like masses, from which may project rudimentary suggestions of a head or of extremities, or they may appear as spherical masses, all traces of head or of limbs being wanting. Such amorphous forms probably originate under conditions due to early obstruction of the allantoic veins, followed by insufficient nutrition and subsequent death of the impaired heart, associated with an inadequate centrally located channel for the return of the blood. In consequence of the stasis so induced, marked œdema of the entire acardius occurs, followed by arrested development or degeneration of the organs; in extreme cases the globular, skin-covered mass retains little resemblance to the fetal form.

DOUBLE MONSTERS.—These malformations constitute a class of joined twins (*gemini conjuncti*) in which the union involves a part of the axial portions of the two bodies. The latter may be *equal* in their development, or one twin may be so retarded in its formation and nutrition that the united individuals are conspicuously *unequal*, even to the extent of the less favored becoming a parasite.

Equally developed united twins present three types:

1. *Anterior duplicity*, or *posterior union*, in which the junction is limited to the lower end of the body axis.

2. *Posterior duplicity*, or *anterior union*, in which the embryos are connected at their cephalic extremities; either the head alone, or in conjunction with a variable part of the adjacent trunk, is involved, leaving the posterior or inferior end of the bodies free.

3. *Middle union*, in which the junction extends from the umbilicus upward for a variable extent.

ANTERIOR DUPLICITY, in which the junction involves the pelvic region, occurs in two forms: (*a*) with *dorsal union*, (*b*) with *ventral union*.

(*a*) *Pygopagus*, the term applied to anterior duplicity with dorsal posterior union, presents a rare form of double monster characterized by a connected pelvic region, with the dorsal surfaces of the twins directed toward each other. The navel is double, the umbilical cords converging toward a common placenta. The axial skeleton of such monsters includes a single coccyx and sacrum common to both individuals, from which spring two spines; rarely the upper part of the sacrum is also double. The innominate bones and the pubic symphyses of the two pelves are present in normal number. In consequence of the obliquity of the dorsal surfaces of the two bodies, the lower limbs, usually fully formed, are so disposed that one pair, belonging to both individuals, lies ventrally and more closely placed than the other. The digestive tubes remain distinct until near the termination of the large gut, where the two recta join and open by a common anus located between the more dorsally situated pair of lower limbs. The spinal cords unite at their inferior extremities to form a common conus with filum terminale. The urogenital tracts show slight fusion of the lower segments; thus associated with a single vulva, the urethra, bladder, vagina, and uterus remain separate. The fact that within a single scrotum four testicles have been found, is readily explained by recalling the original intra-abdominal location of the early sexual gland and its subsequent descent. In a pygopagus examined by Marchand, the abdominal aorta and the venæ cavæ of the two fœtuses joined.

This form of double monster is of especial interest on account of the possibility of life being continued for years, as in the instances of the sisters Christine and Millie, who were born in 1851 and are still alive. A number of pygopagi have been described, of which the most remarkable are the "Hungarian sisters," the "North Carolina twins," and the "Bohemian twins."

The "Hungarian sisters," Helen and Judith, were born in Szony, Hungary, in 1701. They were united at the second sacral segment, below which the sacrum and coccyx were single. The common anus lay between the right thigh of one and the left of the other, and was the termination of a single rectum. In front was a common vulvar orifice, into which two vaginæ opened; the clitoris, nymphæ, and urethra were distinct for each body. Inclination to evacuate the bowels affected both twins at the same time, but urination was effected separately. The great blood-vessels, the aortæ and inferior venæ cavæ, were fused in the region in which the arterial stems bifurcated. Judith, in consequence of illness, remained permanently backward in strength and general development in comparison with her sister. While the two suffered from smallpox and measles at the same time, they contracted other diseases separately. Menstruation began at sixteen, but subsequently the two sisters menstruated at different times and with varying profuseness. When in their twenty-third year, Judith was seized with convulsions and became unconscious, shortly after Helen was in a condition of collapse, and expired a few minutes before her sister.

FIG. 4650. — Pygopagus. Sacrum, from second segment, and coccyx single. *c*, Fused umbilical cords. (Marchand.)

The "North Carolina twins," Christine and Millie, were born in 1851 of negro parents. The union extended from the first sacral segment to the coccyx. There are two recta having a common anal opening, defecation occurring at different times. There are two urethræ and two vaginæ, the labia blending at the posterior margins to give the impression of a single vulva. Menstruation takes place at the same time in both. Common sensibility exists to a limited degree, since one sister can recognize and imperfectly locate touch on the lower extremity of her mate; likewise each knows when the other moves her leg without being able to decide which limb it is.

The "Bohemian twins," Rosaline and Josepha Blazek, were born in 1878. The union is latero-posterior and involves sacra and the lower lumbar vertebræ. The two anterior legs are much closer together than the posterior, the former being moved forward with the outer sides of the feet first, to be followed by the posterior pair with the inner sides of the feet directed forward. In this manner the twins are capable of rapid locomotion or even a quick run, although the stronger girl is able to walk naturally forward and draw after her the weaker sister, who then walks backward.

(*b*) *Ischiopagus*, anterior duplicity with posterior ventral union, is characterized by junction in the pelvic region so related that the right pubic bone of one pelvis fuses with the left pubic bone of the other, the ventral surfaces of the two sacra facing each other. The common pelvic ring thus constituted may be subdivided by an osseous bridge formed by the united coccygeal bones. The body axes may correspond in position, thus forming a straight line, or they may be placed so as to include a very obtuse angle. The continuous ventral body surface contains a single navel. The pelvic organs are often fused and the anus may be single or double; likewise the genital organs. When, however, the latter are in duplicate, they are so placed that each is common to the two bodies, the right and left parts belonging not to one individual, but one to each.

FIG. 4651.—Pygopagus. "Christine and Millie." (Pancoast.)

The lower limbs may be well developed and, when the body axes correspond, are placed at right angles to the latter. When, however, the axes of the two individuals are placed at an angle, the consequent approximation of the lower limbs on one side may result in more or less complete fusion, or these members may be entirely suppressed, and only two lower extremities be developed. In such cases, one limb belongs to each body. Gemmill [54] has very carefully described the anatomical details of the ischiopagus tripus represented in Fig. 4653. Atresia of the urethra and anus, on one or both sides, is common in these malformations, in consequence of which defects ischiopagi seldom survive for any length of time. Sometimes conspicuous discrepancy marks the development of the twins, one remaining very rudimentary, the thorax and head being wanting, although the extremities are present. Such forms constitute the *ischiopagus parasiticus* of certain authors.

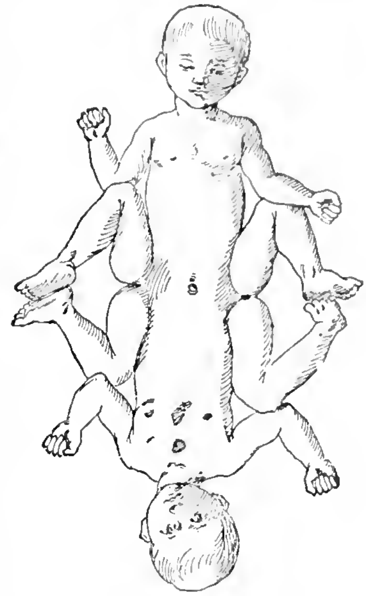

FIG. 4652.—Ischiopagus. (Levy.)

Ischio- or *ileo-thoracopagus* is the name applied to double monsters in which the ventral or latero-ventral union includes the entire trunk. While the presacral portions of the spines are double, the heads being always separated, the pelves are so united that the more approximated ilia are rudimentary or are entirely absent, in which case the two sacra are fused. The more ventrally situated iliac bones, together with the corresponding lower limbs, are well formed. The thoraces of the twins are conjoined ventrally by means of a common sternum, while they are continuous on the dorsal aspect. The upper limbs may all be present (*ischio-thoracopagus tetrabrachius*); or those most closely approximated may be fused into a single member, which may be well developed or very rudimentary. In other cases these limbs fail to develop, thus producing the dibrachial type, one of the remaining pair belonging to each body. The lower extremities are subject to the same arrangements, varying from the full complement to a single pair. The external genitals and the anus are single and common to the two bodies, notwithstanding the presence of double uteri; likewise the bladder is single. The digestive tube exists in duplicate until toward its lower end, the two stomachs being arranged with pylori converging. The thoracic viscera remain partially double, although at times the two hearts are enclosed within a common pericardial sac. An interesting case in the Wistar Institute of Anatomy possessed a heart of which the two sides were contributed each by one fœtus, an intermediate rudimentary auricle and ventricle being the common possession of both. There were three lungs, the intermediate or middle one possessing five lobes. The kidneys in this case were represented by two large and a small intermediate organ. The ischio thoracopagi type of duplicity is not incompatible with prolonged life, as conspicuously shown by the Tocci brothers, who have survived since 1877. According to Virchow, who carefully examined these united twins, it is probable the spinal cords

FIG. 4653. — Ischiopagus Tripus. (Gemmill.)

were separate. The functions of the two children were entirely independent, as well as the reflex movements and sensation of the two lower limbs, one of which belonged to each body. Rita-Christina (1829) and Marie-Rose Drouin (1878) are other noted examples of this form of duplicity; they survived eight and seventeen months respectively.

FIG. 4654.—Ischio-thoracopagus. "Tocci Brothers." (Hirst and Piersol.)

INCOMPLETE ANTERIOR DUPLICITIES include a group of malformations distinguished by partial doubling of the cephalic extremity. Although here conveniently noticed in connection with the forms of anterior duplicity already described, the duplications under consideration probably differ materially from the former in their mode of origin, since there is good reason for regarding them as the results of a dichotomous growth involving the cephalic end of a single embryonic anlage, and not, as in the case of the other anterior duplicities, of the posterior union of two distinct embryos.

The malformations in question present varying grades of duplicity from the mere suggestion of doubling to almost complete separation. The most usual condition is that of doubling of the anterior part of the medullary tube and the chorda followed by duplication of the secondarily derived structures.

Diprosopus is the term applied to partial duplicity where two faces are present. While almost the entire cranial portion of the skull may be simple, the facial part is duplicated and so disposed that the faces are turned more or less toward opposite sides. The divergence depends upon the degree of separation, as does likewise the condition of the eyes, ears, and mouth. Where the duplicity is very slight, the more nearly related eyes may be represented by a single organ (*D. triophthalmus*), or the approximated eyes may later entirely disappear (*D. diophthalmus*). On the other hand, four distinct visual organs may be present (*D. tetrophthalmus*). More rarely the mouths may be fused (*D. monostomus*), although they usually remain distinct. In cases in which two complete faces are present, four ears may remain distinct; frequently, however, two fuse, or are suppressed. The nervous axis also shows more or less extensive duplication, although parts which normally occur in pairs, as the cerebral peduncles, frequently suffer reduction in number by the formation of a common mesially situated structure in place of two distinct, closely placed members.

Dicephalus implies a more extensive and complete duplication of the head, and possibly also of the upper part of the vertebral column. When the spine is involved to a considerable extent, the double-headed monster properly belongs rather to the results of extensive posterior union than to partial anterior duplicity, the differential test being the single or doubled condition of the pelvic end of the spine and the pelvic organs. Frequent examples of dicephalic monsters are seen in the doubled-headed calves of the popular museums, in which the duplication involves, in addition to the head, only the cervical region. In man a true dicephalus is comparatively rare, since the apparent examples of this malformation are really cases of extensive posterior union.

POSTERIOR DUPLICITY with anterior union occurs in two forms: (*a*) *dorsal union*, limited to the head; (*b*) *ventral union*, involving to a greater or less extent the trunks of the two embryos as far as the umbilicus. Both embryos may undergo full development, or one may remain stunted.

(*a*) *Craniopagus*.—This form of monstrosity is characterized by dorsal union involving the heads alone, the

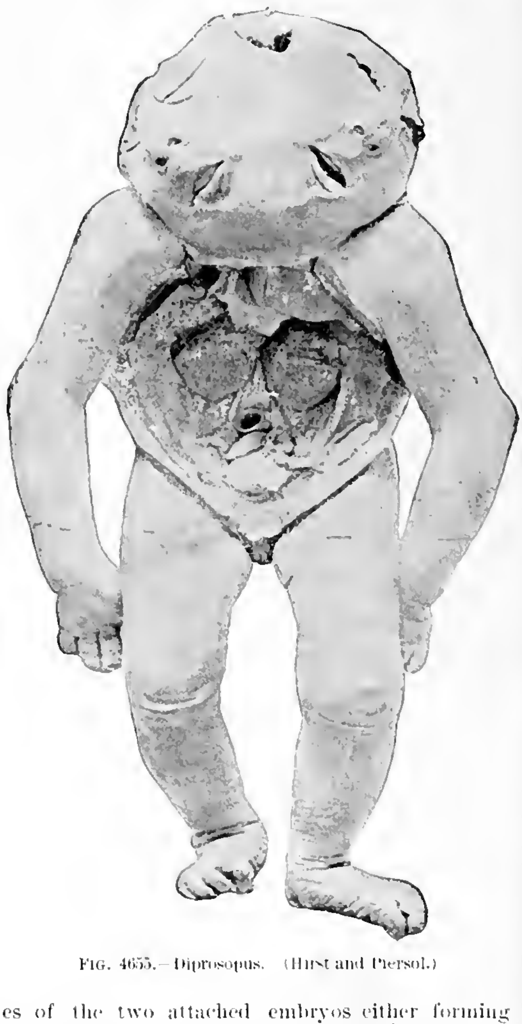

FIG. 4655.—Diprosopus. (Hirst and Piersol.)

axes of the two attached embryos either forming a straight line, or lying at varying angles with each other. The junction may correspond in position with the frontal, parietal, or occipital regions, and usually includes only the integument and cranial vault, the two brains remaining separated by their membranes within a common cranial cavity. It is of interest to note that identical parts of the united skulls are by no means always opposed. This is conspicuous in those rare forms in which partial rotation of the body axes occurs, in consequence of which the faces are turned toward opposite sides. Craniopagic monstrosities are rare and usually short-lived; an exceptional case of craniopagus occipitales, however, is reported as having survived ten years.

FIG. 4656.—Diprosopus. (Ziegler.)

The development of the united embryos may vary so that marked difference is presented in their general growth. This lack of correspondence may be so considerable that the one fœtus becomes an appendage to the more favored, giving rise to a very rare form of head-joined twins, known as *craniopagus parisiticus* (Fig. 4659). One individual is finally represented by a head, alone or in connection with part of the trunk, fused to the autosite, as the better developed fœtus may be termed.

(*b*) *Cephalo-thoracopagus*, or *syncephalus*, applies to posterior duplicities where the union is ventral or latero-ventral and involves the head and the thorax, the pelvic ends of the joined embryos remaining free. The early united twins pass through their development in common, each contributing its quota to the formation of the composite individual. Two faces are formed, each of which belongs half to each embryo. When they are exactly opposite and equally developed, the condition is known as *Janus symmetros*, one face looking ventrally, the other dorsally. More usually there is some lateral misplacement and unequal development as seen in *Janus asymmetros*, in which one face alone is well formed, the other presenting a pair of closely approximated ears. This discrepancy may result in cyclopia, synotia, or obliteration of the oral opening, as well as in suppression or fusion of various parts of the skull. The internal organs of syncephalic monsters present various degrees of union, corresponding in a measure with the extent of the external fusion. In general, however, the viscera retain their independent arrangement. The cerebral divisions may be fully represented, or the adjacent hemispheres may be fused, although the cerebelli, pontes, and medullæ are separate. The two hearts are often so disposed that one lies in relation to the common ventral, the other to the dorsal body surface.

FIG. 4657. Craniopagus. (Barkow.)

MIDDLE UNION.—The ventral or latero-ventral attachment of the embryos forming such malformations extends for a variable distance from the umbilicus upward, at times as far as the head; the pelvis, however, always remains uninvolved. The resulting anterior and posterior duplicity, with intermediate union, suggested the term *duplicitas parallela* applied to these monsters. The umbilicus is single, except in rare cases in which the cord is formed by short converging limbs from the two individuals.

THORACOPAGUS embraces two subdivisions of middle union involving the thoracic region: (*a*) *Xiphopagus* and (*b*) *Sternopagus*. The former presents an attachment at the xiphoid processes, the latter along the sterna of the two embryos.

Xiphopagus is characterized by a more or less extensive epigastric bridge which connects the opposed ventral or ventro-lateral surfaces of the two bodies. The inferior limit of the attachment is the common umbilicus, the upper being marked by the united, usually elongated, xiphoid processes. The thoracic cavities are entirely separate, and divided from the peritoneal sacs by intervening diaphragms. The two livers are usually connected by a bridge of hepatic tissue, although they may remain ununited. In the former case the peritoneal cavities may communicate. The digestive tubes may also open into each other in the vicinity of the stomach or small intestine; in other cases the canals remain entirely distinct.

FIG. 4658.—Craniopagus. (Sanne.)

In a number of xiphopagic twins life has continued for many years. The most noted of these, the Siamese Twins, Eng and Chang, attained the ripe age of nearly sixty-three years before their death in 1874. They were of Siamo-Chinese parentage, being born near Bangkok in 1811. The mother, thirty-five years of age, presented a remarkable predisposition toward multiple births, of the fourteen children which she bore ten being twins. Four daughters preceded the birth of Eng and Chang. The twins were united by a bond extending from the common umbilicus to the xiphoid cartilage, measuring three and one-quarter inches vertically. The connection was of greater length above (one and one third inches) than along its lower margin where it measured almost three inches. The circumference was nine inches, the bridge being broader above than below. Eng, the stronger and better developed of the two, was upon the right, Chang upon the left. Their bodies lacked symmetry, since the inclined and opposed parts were generally less well developed than those turned away. The opposed thoracic surfaces were lacking in rotundity, the outer exhibiting unusual fulness. Chang's chest was deflected to the left owing to marked lateral spinal curvature. The outer arms and legs were stronger than the opposed members

FIG. 4659.—Craniopagus Parasiticus. (Dönitz.)

The brothers were married when thirty-two years old and became fathers of large families, Eng having twelve and Chang ten children; of these twenty-two children all were normal except two of Chang's, who were deaf-mutes. Three years before Chang's death he was stricken with hemiplegia of the right side, from which he never entirely recovered. In January, 1874, Chang developed bronchitis which, aggravated by imprudent exposure, led to pulmonary oppression and inability to lie down without discomfort. After both had fallen asleep, Eng awakened to find his brother dead. Within a little more than two hours of this discovery Eng's death quietly ensued, consciousness being retained almost to the last.

FIG. 4660.—Cephalo-thoracopagus with Janus-Head; other face presented malformed eyes, nose, and mouth. (Hirst and Piersol.)

The autopsy disclosed the bond of union to consist, in addition to the integument, connective tissue, fat, and aponeuroses, of a bridge of hepatic tissue, three inches long, one-half inch wide, and one-quarter inch thick, which arose on both sides, directly above the longitudinal fissure. Two peritoneal pouches on each side, extended transversely until separated by a vertical median septum. Extensions of muscular tissue of both diaphragms were represented by a broad slip from Chang, which was inserted into ensiform process of Eng, and a similar but smaller band which passed to Chang, supplemented by two additional slips extending from Eng's diaphragm to that of Chang. The blood-vessels within the bond of union included a terminal and

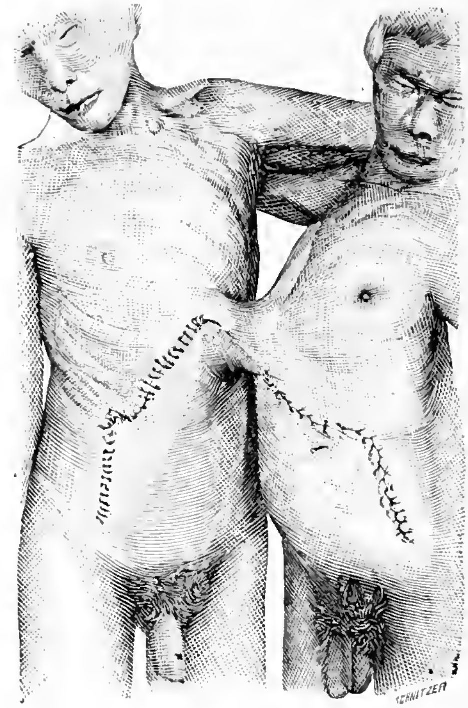

FIG. 4661.—Xiphopagus. "Siamese Twins." (Pancoast.)

an extrahepatic branch of the portal vein, branches of the hepatic artery, and some terminal twigs of the right internal mammary artery of Eng.

In this connection it may be of interest to note the operation undertaken by Prevost for the separation of the Brazilian xiphopagic sisters, "Rosalina" and "Maria." According to the letter published in the *Medical Record* (vol. lviii., 1900, p. 108) one sister, Rosalina, entirely recovered from the operation, the other succumbed.

FIG. 4662.—The Hepatic Isthmus across the Connecting Band of "Siamese Twins" Eng and Chang.

Sternopagus implies an upward extension of the attachment, so that the sterna are fused into a single bone at the upper border of the common thorax. In cases in which the union is very intimate, the manubrium may receive the four clavicles of the two individuals.

The hearts may remain distinct, or they may be fused to form a single tubular organ, from either side of which the great vessels are given off. When two hearts are present they usually are enclosed within a single peri-

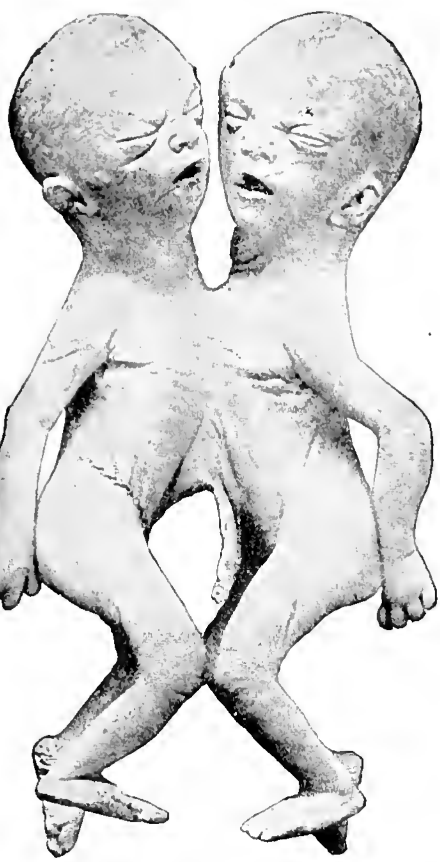

FIG. 4663.—Thoracopagus. (Hirst and Piersol.)

cardial sac. The common thoracic cavity is separated from the abdominal space by a single diaphragm. The middle portion of the digestive tube, including the greater part of the jejunum and ileum, is single. Above the jejunum, embracing the duodenum, the stomach and the œsophagus, and likewise below the position of the vitelline duct, the digestive canal is double. The livers are blended, more or less, into one common mass. The genitalia are separate and distinct, each body having its own set.

While the limb complement of the sternopagic twins may be normal, deviations from a ventral toward a ventro-lateral type of union, due to convergence of the spinal axes, sometimes result in the blending of the approximated upper extremities, the third arm thus produced being the joint contribution of the two embryos. Such limbs are sometimes very rudimentary. Sternopagi are usually born dead; if alive, they survive only a short time in consequence of their defective heart development.

MODE OF PRODUCTION OF DOUBLE MONSTERS.—Apart from the more speculative considerations of the causes leading to double monsters which have already been briefly sketched, the manner in which duplicities are formed calls for notice. Attention has been directed to the two prominent opposed views—fission and fusion—which have prevailed, and the arguments have been reviewed that have influenced the adoption of the fusion theory as offering the most plausible explanation of the production of double monsters. With the exception of the dicephali, in which dichotomous growth of the head end of the anlage may consistently be regarded as the mode of production, early union, more or less extensive, of the originally distinct but closely related, anlages seems most worthy of acceptance as the principle upon which double monsters originate. The accompanying diagrams have been suggested by Marchand as hypothetically illustrating the most plausible genesis of the anterior and posterior types of duplicity. In Fig. 4664, *A* represents the assumed early stage in which the two closely related anlages lie upon the common embryonic area, united to the chorion by the diverging belly stalks. With advancing development the latter become more widely separated, while the cephalic ends approach until they meet and union takes place; the umbilical vesicles meanwhile have become defined as two conspicuous sacs, one largely occupying the ventral surface of each embryo. The common amnion invests the dorso-lateral surfaces of both embryos and grows between their diverging belly stalks. *C* represents a later stage in which more marked fusion of the head ends has taken place, while at the same time the belly stalks are more widely separated, thus foreshadowing the later diomphalic or independent condition of the umbilical cords.

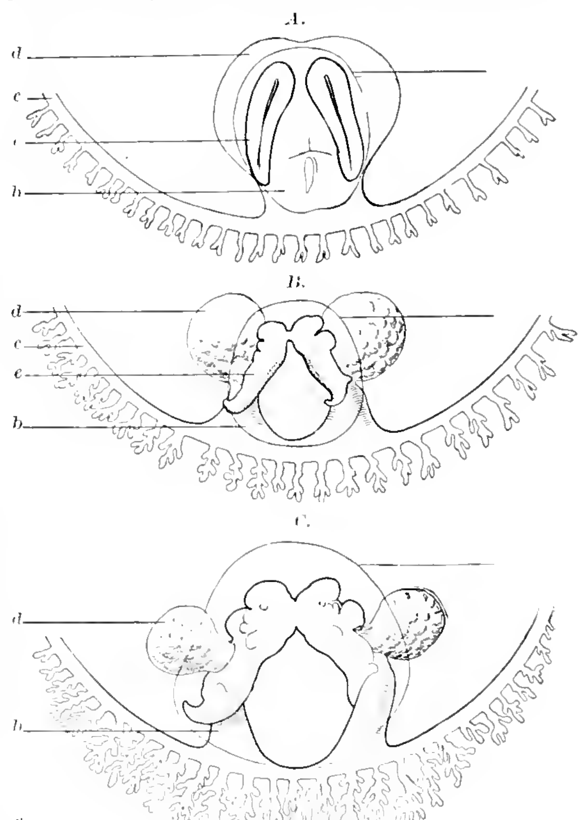

FIG. 4664.—Diagrams Illustrating Production of Hypothetical Double Monster with Anterior Union. Cephalopagus. *A*, The two embryos, on a common germinal area, are almost in contact with cephalic poles; united to chorion by closely placed belly stalks. *B* and *C*, later stages after union has been effected. *a*, Common amnion; *b*, belly-stalks; *c*, chorion; *d*, yolk-sac; *e*, embryo. (After Marchand.)

Rapid and extensive early separation of the belly stalks, together with rotation of the embryos, accounts for the various types of craniopagic twins.

In a similar manner the formation of the opposite condition of posterior union may be assumed to take place. (Fig. 4665.) The production of pygopagic twins, however, assumes the continued close relations of the belly stalk, with more or less divergence of the cephalic poles until, in certain cases, the axes of the two embryos correspond. The rotation and ventral type of union is associated with the retention of a common umbilical vesicle

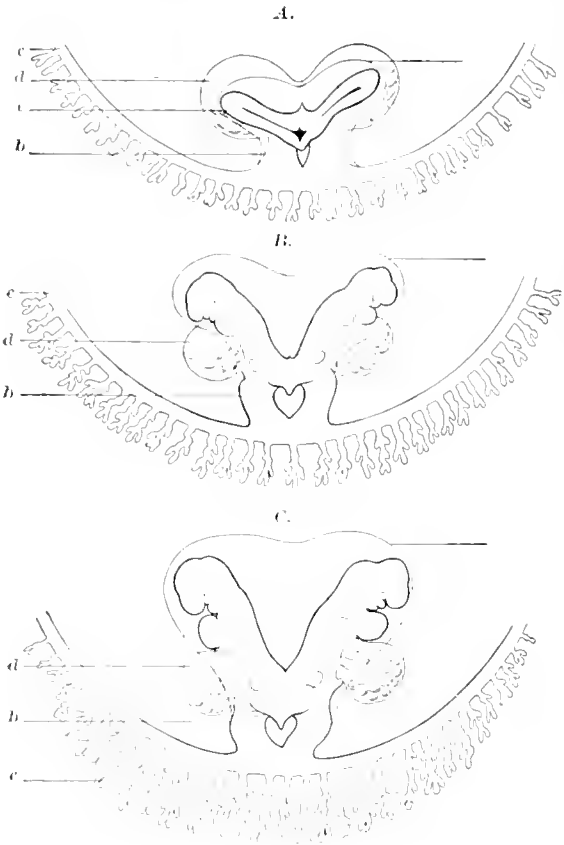

FIG. 4665.—Diagrams Illustrating Production of Hypothetical Double Monster with Posterior Union. Pygopagus. *A*, Very early stage; at caudal end primitive streaks fused into common tract; cephalic ends diverge. United embryos fixed to chorion by closely placed belly stalks. *B* and *C* later stages. *a*, Common amnion; *b*, belly stalk; *c*, chorion; *d*, yolk sac; *e*, embryo. (After Marchand.)

(vitelline sac) and single umbilicus. The assumption of these stages is hypothetical, and based upon theoretical possibilities rather than direct observation.

Multiplicities.

A systematic classification of pleural conceptions (including the cases of three, four, five, and possibly six at one birth) would call for the recognition of *complete* and *incomplete* multiplicities. The former again embrace the *monochorionic* group, of which the *equal* and *unequal* triplets are the best known representatives.

Monochorionic triplets are very infrequent, although a number have been described. The common chorion may enclose the three separate amnionic sacs, the umbilical vessels anastomosing within the placenta. Two authentic cases of monochorionic quadruplets have been recorded and an observation of five fœtuses within a common chorion has been credited to Pigné. Other instances of quintuplets have been reported, but these, as in the case reported by Kölliker, include the association of monochorionic triplets with similar twins. The example of plural births reported by Vassali in 1888 recording the extraction of six fœtuses, four males and two females, probably falls within this category. Kerr and Cookman have recently reported (*Medical Press and Circular*, May 27th, 1903) a remarkable case of six at one birth to which they were called. The mother, a native woman of Accra, West Africa, gave birth to five boys and one girl; all were alive when born, but succumbed between the second and fourth day. The girl and one boy had a placenta each, the remaining four children being attached to two placentæ. The mother, who recovered, exhibited a noteworthy predisposition toward pleural conceptions, three former pregnancies having yielded four, three, and three children respectively, making a total of sixteen in four confinements. The evidence sustaining a reputed instance of the birth of seven children, two boys and five girls, at Hameln in 1600, to which Barfurth[55] has called attention, is too uncertain to be convincing. Were the case satisfactorily authentic, here, too, the presence of more than one ovum and chorionic sac must be assumed as probable.

FIG. 4666.—Tricephalus. (Reina and Galvani.)

The occurrence of a malformed fœtus in company with two or even three others within a single chorion is extremely rare, only three trustworthy cases being recorded. That described by Soemmering presented four female fœtuses within a common sac, three being normal while the fourth was an acephalus.

FIG. 4667.—Dipygus Parisiticus. "Laloo." (Hirst and Piersol.)

Triple Monsters represent the rarest of all malformations. While a small number of such abnormalities have been observed among the lower animals, only a sin-

Fig. 4668.—Dipygus. (Hirst and Piersol.)

gle well-authenticated example of a human triple monster has been recorded by Reina and Galvani. The deformity was born in 1831, after a difficult labor lasting four days, necessitating the perforation and amputation of the first and second heads and the perforation of the third. Two spines were present bearing one and two heads respectively; the spinal columns were separate to their lower ends, although the sacra were very closely related. The pelvis included four iliac, two ischiac, and two pubic bones, the poorly developed medianly placed ilia being united by cartilage. The thoracic cavities were separated by a thin septum, each enclosing a heart. The abdominal cavity was large, the contained organs included a single stomach and an œsophagus that divided a short distance above its lower end; one of the resulting branches again divided, each head thus being provided with its own œsophagus. A similar arrangement was present in the trachea. The separation was apparent externally only on the neck and head, the unusually broad thorax seemingly being single. A third rudimentary upper extremity projected dorsally. The lower half of the body was normal, as were also the male genital organs.

The interpretation of the triplicity just described is to be found in the assumption that the anterior end of one of the primary anlages, which have undergone posterior fusion in the production of the ischiopagus, has been affected by dichotomous growth. The result of the latter is seen in the closely associated heads surmounting one spine.

Asymmetrical Duplicity.—Attention has been already called to the possibility that one of originally equal embryos which unite to form double monsters may suffer impairment of nutrition to such extent that its further imperfect development depends upon connections with the more fortunate mate. Such "parasites," therefore, result from secondary changes which affect embryos which were at first symmetrical. The continued nutrition and development of a part of the parasite, with the atrophy and disappearance of those parts less favorably situated, account for the remarkable cases in which a well formed head is attached to that of the autosite. In other instances the cephalic end of one embryo becomes atrophic and is drawn within the body of the other, surrounded by the ventrally closing parietal plates.

Mention may here be made of two conspicuous examples of asymmetrical duplicity. The one, "Laloo"—familiar to many on account of his museum notoriety—represents the type of unequally developed thoracopagus, termed *dipygus parasiticus*, or gastro-thoracopagus dipygus. The "parasite," attached from the umbilicus to the xiphoid process of his host, exhibited neither voluntary movements nor responded to Laloo's will. An anus is not present, but a small penis occasionally voids small quantities of urine. The other malformation (Fig. 4668) is a remarkable instance of the rare form of posterior duplicity known as *diphygus*. In the case figured the duplicity begins at the third lumbar vertebra. She was married and became pregnant on the left side, both sets of organs being, however, functionating. Micturition and defecation take place independently on the two sides, but menstruation occurs at the same time. Anterior fusion of two closely placed converging embryonic anlages probably accounts for this rare type of malformation.

The asymmetrical duplicities now to be considered include, on the contrary, the *true parasitic double monsters* which result from anlages in which primary inequality and subsequent asymmetry of form and size are characteristic features. The inequality of the anlages may be so marked that the parasite presents little or no external resemblance to a fœtus; in other cases the dependent embryo may develop parts, as extremities, which are fairly well formed. In addition to such external attachments, or *implantations*, other parasites exist as *inclusions* within the autosite, having been drawn into the latter by the closure of the body walls, or lying from the earliest stages within the mesoderm.

As introductory to the consideration of the rudimentary fœtal or parasitic growths encountered in various parts of the body, distinction must be made between der-

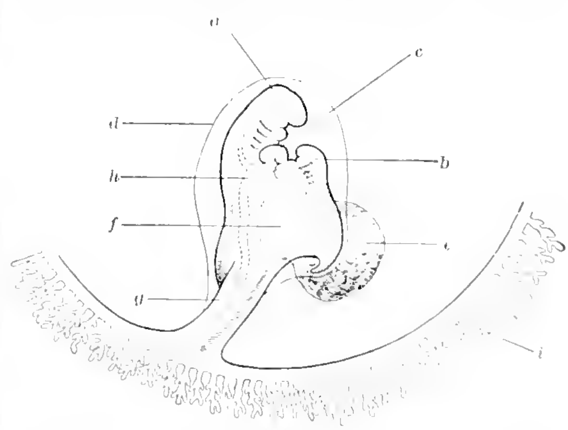

Fig. 4669.—Schematic Representation of Relations of Embryos of about Third Week in Production of Parasitic Duplicity. *a*, Autosite; *b*, parasite; *c*, heart of former; *d*, common amnion joining common yolk sac (*e*) around *f*; *g*, common belly stalk; *i*, chorion. (After Marchand.)

moid cysts, arising from invagination and displacement of portions of the elements from the neighboring skin, and the true parasite tumors or *teratomata* originating by differentiation of tissues from the three germ layers derived from the independent although imperfect development of a separate anlage. In the former case the tissues of the skin cyst include only those that ordinarily may

FIG. 4670.—Epignathus. (Ahlfeld.)

develop from the integumentary layers, their position being unusual owing to the dislocation of the aberrant cells ("Keimverirrung").

It is necessary, therefore, to recognize that simple dermoid cysts occur in many localities which may be the seats of true fœtal growths. The distinction between the latter and the simple skin cysts is by no means always easily made. In doubtful cases, in which evident fœtal structures are unrecognizable, the crucial test in establishing the parasitic nature of the growth is the presence of tissues and structures derived from all three germ layers, which cannot be attributed to transplantation of neighboring structures.

Although differing little in the principles governing their genesis, it is convenient for description to group parasitic duplicities according to the region of the autosite to which they are attached.

CEPHALIC PARASITES.—*Epignathus* is the term applied to a well-known group in which the rudimentary parasite is attached to the base of the skull or the palate and appears as a mass protruding from the mouth. The parasitic tumor is usually enclosed within an envelope of skin containing hair bulbs and sweat glands. When of small size, however, the tumor may lie almost entirely or wholly within the oral cavity, in which case a covering of mucous membrane replaces more or less completely the integument. The mass most frequently consists of cysts, cavities, and intervening slightly differentiated embryonal tissue. In other cases the tumor contains easily recognized fœtal structures, including perhaps skin, epithelium, hair, teeth, cartilage, bones, fat, and brain substance. Parts of a rudimentary intestinal canal, as well as normal hepatic tissue, have been found as constituents of epignathic parasites.

In contrast to the amorphous types are the rarer instances in which the parasite presents conspicuous fœtal characters, such as partly developed inferior extremities. Krentzmann[56] described an epignathus in which a tumor depended from the cleft hard palate of the autosite, being united by a stalk to the vomer and base of the skull. The tumor, the size of a fist and covered with hair, at one point bore an imperfectly developed set of external female genitalia, possessing labia majora and minora and a tube representing the vagina. These lay between two rudimentary lower extremities.

As a great rarity the parasite may be attached to the region of the orbit from which a tumor-like mass protrudes. Ahlfeld[57] has described and figured (Fig. 4671) a remarkable case of this kind in which a buttock and left lower extremity protruded from the left orbit of a well-formed child. In the vicinity of the left oral angle projected an additional tumor. Broer and Weigert[58] also record a case in which the right eyeball was connected with a tumor, the "size of an orange," that extended outward from the orbit. Microscopical examination revealed within the orbital fat the presence of cartilage, bone, epidermal masses, mucous gland cysts, portions of the digestive and respiratory apparatus.

Encranius embraces a group of fœtal inclusions in which the parasitic anlage lies partly or wholly within the cranial cavity of the autosite. Based on their mode of origin (see page 693) and the position of the anlage, as within or without the skull, the intracranial parasites may be divided into *primary* and *secondary inclusions*. The former undergo but slight development and remain rudimentary, appearing as irregular tumors attached often in the vicinity of the sella turcica or beneath the dura in other localities. The immediate neighborhood of the pituitary body is a favorite location, not only for dermoid cysts derived from aberrant cells which have gained the interior of the skull by means of the early invagination producing the oral portion of the pituitary body, but also for growths which contain rudiments of various tissues and organs. Beck[59] found a tumor, the size of a walnut, on the sella turcica which contained cartilage, bone, myxomatous tissue, cyst lined with ciliated epithelium, and fourteen teeth; structure resembling thyroid gland was also present. Such tumors may remain for years without further growth, as in the case recorded by Eberthr,[60] of a woman of seventy-five, in whom the teratome contained nervous, muscular, and lymphoid tissue.

It may be assumed that parasitic anlage, are drawn into the interior of the future skull during the early closure of the neural canal, to become later enclosed by the brain mass. Strassmann and Strecker[61] described a teratoma in the right lateral ventricle which probably thus gained early access from the dorsal surface. The tumor was of the size of a walnut, riddled with spaces, contained a cyst lined with simple and stratified epithelium, nervous

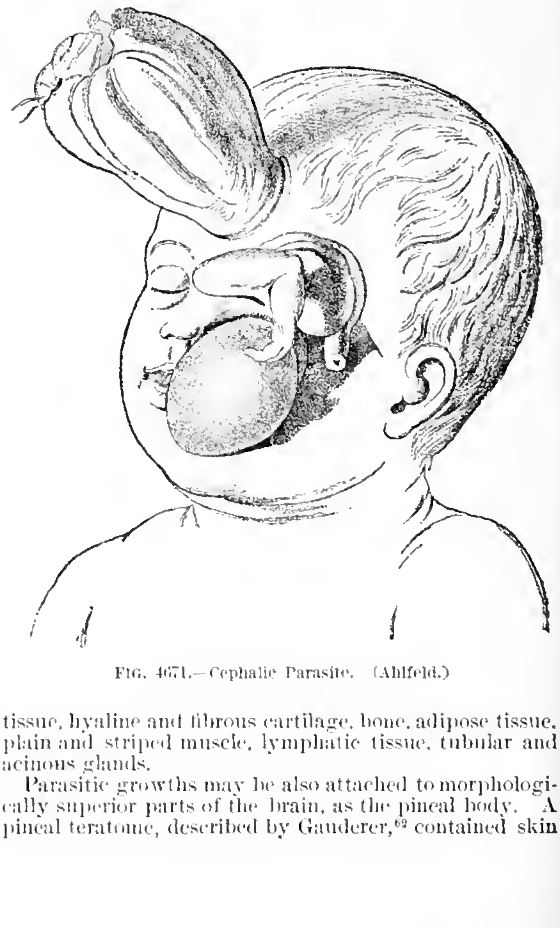

FIG. 4671.—Cephalic Parasite. (Ahlfeld.)

tissue, hyaline and fibrous cartilage, bone, adipose tissue, plain and striped muscle, lymphatic tissue, tubular and acinous glands.

Parasitic growths may be also attached to morphologically superior parts of the brain, as the pineal body. A pineal teratome, described by Gauderer,[62] contained skin and sebaceous glands, cartilage, bones, plain muscle, adipose tissue, and columnar epithelium.

The *secondary inclusions* may present externally fœtal characters, such as more or less developed limbs attached to a rudimentary trunk. The escape of the inclusion may be through the base of the skull into or beyond the mouth, the protruding mass then resembling an epignathus. In rare instances the parasite may project from the cranium of the autosite. Aretaos[63] described a very remarkable case in which, in addition to a rudimentary inclusion, an acephalic parasite protruded from the skull of the autosite.

Lovett and Councilman[64] have also recorded an instance of multiple inclusions in a child of three weeks, which presented a scrotal and intracranial teratoma containing representations of all three blastodermic layers.

The encranial parasites above described imply the production of more or less characteristic fœtal structures from the development of independent anlages capable of giving rise to all types of tissue. The inclusions from such anlages may, therefore, be regarded as true parasites, although they may remain rudimentary. To be distinguished from the latter are the intracranial dermoid cysts originating from the isolated and transplanted masses of epidermal elements, which ordinarily produce the prototypes of the tissues found within the intracranial growths. The latter should not be included within the true parasitic inclusions.

Cervical Parasites or Teratomata comprise the true fœtal inclusions attached to some part of the region formed by the visceral arches. Such parasitic growths appear as cystic tumors, covered with integument and extending a variable distance along the neck and lower jaw. In addition to the cysts usually present, the tumors contain more or less developed fœtal structures, including bones, teeth, parts of the head, and extremities. A cervical teratome in a child of two years, described by Brunker,[65] extended from the zygoma to the third rib and contained brain tissue, fat, cartilage, striated muscle, glands, and a rudimentary eye. Usually the seat of the growth is less extensive and is limited to the lateral cervical region. Instances are recorded of attachment to the parotid and the oral region, the latter cases forming a transition between the cervical and epignathic groups. Gurlt and Slomann both have described cases in which teeth were conspicuous; in one instance in a child of five years, both milk and permanent teeth were present and corresponded in form and size to the age of the patient.

Thoracic Parasites.—Closely associated with the teratomata of the cervical region are the dermoid growths occasionally encountered within the anterior mediastinum in the vicinity of the thymus gland or its remains. That the migration of this organ from its original relation with the third pharyngeal pouch to the mediastinal space is the probable means of transplantation of the primary tissues giving rise to the dermoids under consideration is suggested by the intimate relations between the outer and inner germ layers in the occluding membranes closing the visceral clefts in mammals. Although the primary thymus anlage is entodermic in origin, the proximity of the ectoderm lining the external furrows and the important changes in the relation of the arches effected by the formation, and later closure of the sinus precervicalis render the transportation of ectoblastic and mesodermic tissue in connection with the migration of the thymus highly probable. Additional evidence of close association is had in the presence of thymus tissue in cases reported by Marchand and by Pinders.

As shown by the series of forty cases tabulated by Christian,[66] the great majority of mediastinal dermoids are to be regarded as tumors of ectodermal origin, since of these cases only two can be classified as true teratomata, the derivatives of all three germ layers. These conclusions agree with the results of the studies of Pflanz[67] and of Wilms.[68] A few cases, however, such as recorded by Virchow,[69] Marchand,[70] Ekehorn,[71] and Fletcher,[72] give evidence of being true teratomata. The possibility of other congenital tumors of the lower anterior mediastinum being the result of inclusions at the time of the closure of the ventral body walls cannot be ignored, although a branchiogenetic origin is undoubtedly the more common. Extensions to the neighboring lung constitute the pulmonary dermoids sometimes described.

Although among the lower animals examples of parasitic anlages attached to the dorsal body surface are occasionally observed as rudimentary limbs projecting from

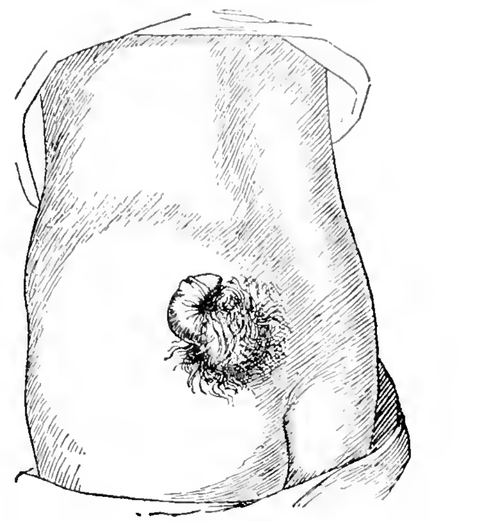

Fig. 4672.—Supernumerary Penis on Back. (Windle.)

the back, such malformations have not been encountered in the human subject. In this connection mention should be made of the remarkable case (Fig. 4672) described by Windle[73] of a young man who, in addition to normal genitalia, possessed over the lumbar vertebræ an elevation similar to a mons from which projected a small but well-formed penis, capable of erection, although imperforate. Windle refers to a somewhat similar case, recorded by Tsortis, of a soldier of twenty-one, who bore, below the left scapula, an almost complete set of female external genital organs. A small cavity between the labia resembled a rudimentary vagina, above which was a clitoris-like tubercle. These cases can be explained only on the assumption of the partial development of a second, originally independent embryonic anlage.

Sacral Parasites and Teratomata.—Of all forms of parasitic inclusions those occurring in the sacral and perineal regions are most frequent. They usually appear as cystic tumors attached to the sacrum, on either the anterior or posterior surface, or to the coccyx. The tumor is covered with integument directly continuous with that of the autosite, and consists usually of several cysts. Not infrequently the position of the teratome is not median, but to one side; in such cases often a second enlargement, consisting of a simple cyst, lies at the side of the larger nodulated parasitic growth, the two tumors sometimes occupying the opposite sides of the coccyx. Within the compartments of the teratome are found more or less striking evidences of its fœtal origin. These may include various epidermal structures and connective tissue, cartilage, bone, muscle, and nervous tissue, as well as parts of the spine, the digestive tract, and glands. In exceptional cases rudimentary extremities, both upper and lower, may be present and even free, being dependent from the tumor. In the classic and unique case of Anna Przenosly described by Ammon, in the third year a small congenital tumor opened and revealed a supernumerary leg which after seventeen years was removed by amputation. The presence of considerable masses of muscular tissue within the sac surrounding the inclusion may give rise to movements as in the two instances recorded by Preuss and by Ahlfeld. In the infant observed by the latter, the motion was produced by contractions of a sheet of striped muscle beneath the covering of the tumor and not by true fœtal movements.

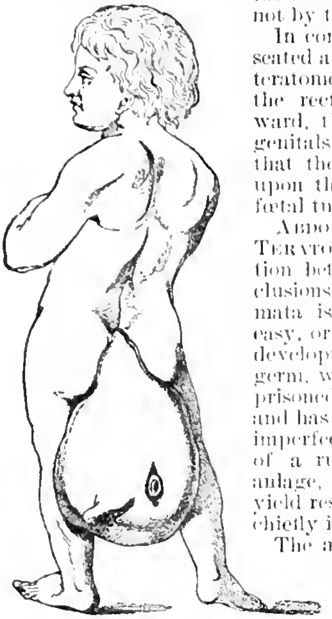

FIG. 4673.—Child with Sacral Tumor. (Löffler.)

In consequence of the deep seated attachment of the sacral teratomes, the perineum and the rectum are pushed forward, the anus and extended genitals being so displaced that they usually lie directly upon the anterior part of the fœtal tumor.

ABDOMINAL PARASITES AND TERATOMATA.—The distinction between true parasitic inclusions and embryonal teratomata is by no means always easy, or indeed possible. The development of an independent germ, which has become imprisoned at an early period and has undergone only a very imperfect evolution, and that of a rudimentary embryonal anlage, producing a teratoma, yield results which often differ chiefly in degree.

The anlage of the parasitic inclusion may lie, theoretically at least, embedded within the abdominal wall of the autosite, or it may be included within the body cavity. The entire number of adequately described and undoubted abdominal fœtal inclusions is small, probably less than forty. As an example of the very rare intraparietal type of inclusion the case mentioned by Himly [74] stands almost alone. Autopsy of a female child of two and one-half years revealed a cystic tumor in the epigastrium which contained a fairly well-formed fœtus, with, however, defective extremities and head.

The intra-abdominal inclusions, or *epigastric parasites*, are found most commonly in the vicinity of the lesser peritoneal sac, between the layers, or at the root, of the transverse mesocolon, being an especially favorite location. Since, as shown by Paquy,[75] the true fœtal inclusions always lie supra-umbilical and closely connected with the alimentary canal, Lexer [76] regards their usual intimate relation to the lesser peritoneal sac as due to migration induced by the increasing volume of the liver and the transverse displacement of the stomach. The fœtal parasite is usually enclosed within an envelope, composed of mesenteric or retroperitoneal tissue, to which the rudimentary embryo may be attached. Sometimes the fœtal characters are so well pronounced that spine, head, and extremities are recognizable; in other cases only rudimentary organs are present. The sac surrounding the inclusion is closely united with the adjacent organs, the blood-vessels of which communicate with those of the parasite and provide for its nutrition. Not infrequently the rudimentary fœtus exhibits distortion, the result of progressive mechanical disturbances as well as of faulty development. Under such conditions the inclusion may become pressed into a shapeless mass.

Spontaneous movements have been noted within the cyst containing the parasite. Klebs [77] describes a case of an infant in which independent motions were noted within an abdominal tumor. The child died a few weeks after birth, and presented, on post mortem examination, a cyst composed of peritoneum and amnion beneath the transverse colon. An artery passed from the aorta of the host to the cyst and thence by a short umbilical cord to the parasite. The latter was of an irregular ellipsoidal form and consisted of an imperfect spine and pelvis, a skull of considerable size containing a distinct brain mass, a digestive tube with unusually wide, large intestine, a liver, and rudimentary lungs and heart. The extremities were represented by poorly developed and stunted limbs. External genitals were absent.

Another remarkable instance of abdominal fœtal inclusion is the classic case recorded by Highmore.[78] The subject, when a boy of seven, developed a marked abdominal swelling attended with severe pain. Succeeding a period of temporary relief until the fifteenth year, the distress returned, death occurring in consequence of intestinal hemorrhage. During life marked pulsations were recognizable in the tumor, sensitive on pressure; the movements were felt by the patient, who declared that his abdomen contained something living. The autopsy disclosed an irregularly oval, sack-like tumor, weighing over four pounds, attached along the entire extent of the duodenum, which freely communicated with and formed a part of the sack. The latter contained an imperfect fœtus with stunted trunk, two upper and one lower extremities, and a very rudimentary head consisting of scalp to which hair a foot long was attached. The nutrition of the parasitic fœtus was maintained by a short cord which established the connection with the vascular walls of the sack.

Ballantyne [79] describes an abdominal teratoma in a child of three months, the parasite being connected with the lesser peritoneal sac. At one point there was a projection resembling a pair of rudimentary digits; pieces of intestine, teeth, and fragments of bone and cartilage were also present. Paquy records a somewhat similar case in which the omentum was occupied by a tumor consisting largely of cartilage, glandular elements, and abundant blood-vessels.

Although children bearing fœtal inclusions are often still-born, the possession of the parasite is not incompatible with prolonged, and even extended, life, since such inclusions have been discovered in subjects of advanced years. Usually, however, the presence of the parasite induces, after a time, fatal peritonitis.

EMBRYONAL TUMORS OF THE SEXUAL GLANDS.—The sexual glands are the seats of fœtal tumors of great interest by reason not only of their relative frequency, but also of the interesting problems concerning their production. Disregarding for the present the latter, these tumors may be divided into *cystic dermoids* and *teratomata* according to their consistence—sac-like or solid respectively—and the degree of development which they present.

FIG. 4674.—Sacral Teratoma Containing Extremities (*a*, *b*, *c*) of Parasite. (Ziegler.)

Ovarian cystic dermoids, the more common variety of the first group, appear as tumors varying in size from a pea to a child's head. These consist of a tough-walled sac enclosing a fatty mass and hair. The seat of the dermoid is nearly always the sexual gland, the tumor being attached to the adnexa of the uterus by broad adhesions. The ovarian tissue immediately surrounding the growth usually undergoes partial or complete degeneration, although in exceptional cases the dermoid may be almost isolated and connected with the ovary by only a slender stalk. Wilms [80] has established the important fact, confirmed by a number of competent observers, that the embryonal tumors of the sexual glands contain derivatives of all three germ layers, and further, that the development proceeds in general, although modified, in a way similar to that followed under normal conditions.

The inner surface of the dermoid cyst at some point exhibits a projection, villous or less abrupt, which usually bears hairs and also not infrequently teeth. While the more superficial layer of the projection contains the constituents of the integument, including hair follicles and sebaceous and sweat glands, the deeper parts may enclose cartilage, bone, muscular tissue, nervous substance, mucous glands, or suggestions of the digestive and respiratory tubes. Rudimentary mammary glands with nipples, fingers with nails, and retinal pigment are among the rarer additional organs that have been observed in ovarian dermoids. Hepatic, renal, and cardiac tissue, on the contrary, are among the few structures not represented in these tumors. The explanation of these exceptions, as suggested by Wilms, lies in the early assumption by the autosite of the nutrition of the parasitic embryo, which results, after a possible abortive effort at heart formation, in a very imperfect independent circulatory apparatus. In consequence of this relation there is no necessity for the formation of excretory organs, hence the liver and kidneys remain undeveloped and are never found.

Although most frequently encountered in middle life, ovarian cystic dermoids occur at all ages from early childhood to extreme old age.

Ovarian teratomata, or solid tumors, are of much greater rarity than the cystic dermoids. As the latter, so also the teratomes always contain the representatives of all the germ layers. The tissues and rudimentary organs, however, present much less regularity in order and arrangement and hence less resemblance to the fœtus on account of their confused and indefinite disposition and generally less perfect development. These characteristics are due to the mechanical disturbances induced by limitations of space, in consequence of which there follows a displacement of the cells resulting in loss of relations in the anlage and the institution of a process of tumor formation. As shown by Wilms,[81] the solid ovarian teratomata correspond in genesis with the cystic dermoids and differ only in the degree to which the fœtal structures are developed. In view of the slight resemblance that these growths bear to the normal products of conception, Wilms has appropriately named them *embryonoid tumors*.

The *fœtal growths of the testicle* constitute a group homologous with those of the ovary already discussed, in conjunction with the latter forming the distinct class of rudimentary parasites of the sexual glands. Wilms conclusively proved that these growths originate from the testicle and correspond in all important features with those of the ovary. As in the latter so also in the testicle dermoid cysts and solid teratomes both occur; in the male gland, however, in contrast to the female, the cystic dermoids are of extreme rarity, the solid tumors being the form usually encountered. Even these are of great infrequency when compared with the ovarian teratomata. As pointed out by Wilms,[82] in the testicle the conditions favorable for the development and growth of fœtal structures are seldom present on account of the anatomical construction of the organ and its position, hence the formation of rudimentary parasites but rarely takes place, the solid embryonoid tumors being the usual expression of the repressed development.

Dermoid cysts of the testicle, although of great infrequency, occasionally present marked fœtal characters, as in the remarkable case reported by Répin[83] in which an almost complete skeleton, with four limbs, was present. The more usual teratomes evince their embryonal nature by the presence of tissues derived from the three germ layers rather than by an orderly disposition suggesting parts of a fœtus.

These tumors vary greatly in size, the largest being in volume equal to a child's head. They may be entirely solid or contain cysts which may be lined by simple or stratified cuboidal or cylindrical epithelium; in rare cases pigmented as well as glandular cells have been found. The derivatives of the mesoblast are conspicuous in these tumors, being represented often by considerable masses of connective tissue and cartilage, less frequently by bone; adipose and muscular tissues are also not uncommon. The teratomata of the testicle, therefore, are usually met with in the form of adenocystoma, chondroadenoma, chondrosarcoma, adenorhabdomyoma, or other type of composite tumor.

The studies of Wilms leaves no doubt that these teratomata are to be regarded as imperfect expressions of an independent development, and that they in principle are to be regarded as extremely rudimentary parasitic malformations modified by the influence of mechanical disturbance.

Origin of Parasitic Duplicities.

The condition of true parasitic duplicity, as distinguished from dependence secondarily acquired by one of the united twins in consequence of unfavorable conditions of development, implies *primary inequality* of the anlages.

In all forms of double monsters the allantoic circulation of one individual may become impaired or interrupted to such extent that the affected embryo succumbs unless its nutrition is assumed by the more fortunate mate. The donation by the latter may so far suffice that a considerable part of the dependent embryo is maintained, thereby producing such striking forms as "Laloo." When, on the other hand, the union is cranial and the donated nutrition insufficient, only the cephalic end may remain, as in the classic case of Home, in which a well-developed head, attached to the vertex of the autosite, alone represented what was at one time a complete embryo.

The secondary and acquired nature of such parasites is conclusively demonstrated by the presence of the remains of an atrophic umbilical cord attached to the trunk. Since the nutrition of the affected embryo is early assumed by the stronger, the heart of the former atrophies, although instances have been noted in which the hearts of both parasite and autosite have existed within the thorax of the autosite.

The true parasitic duplicities are from the first conspicuously asymmetrical, the dependent embryo being rudimentary or incompletely developed, and more or less enclosed by the body of the autosite. These inclusions present two groups: (*a*) those which are partially surround and hence appear as an external appendage to the host, or are drawn within the body and lie beneath the integument of the autosite; (*b*) those which develop entirely within the autosite, especially in relation to the abdominal cavity. Examples of the first group are seen in the epignathi and the sacral tumors; of the second in the ovarian dermoids.

The exact manner in which the weaker and rudimentary anlage becomes surrounded by the stronger can only be surmised, but it may be assumed with probability as intimately related with the migration of the external layer of the autosite which takes place in connection with the invaginations and the closures incidental to the normal development of the stronger embryo. Such closures occur at the cephalic pole and along the dorsal and ventral surfaces, while the primary oval and branchial invaginations are additional means of transportation. We may reasonably conceive the anlage giving rise to the future parasite as being fixed to the surface and within the amnion of the autosite in the immediate vicinity of such migratory areas; subsequently it is carried within the body and more or less surrounded by the tissues of the autosite to produce a true fœtal inclusion, or *fœtus in fœtu*.

The production and relations of an epignathus or encranius can be clearly referred to the inclusion of anlages which have suffered displacement during the formation

Teratology.

of the primary oval invagination and of the brain case respectively. In other cases, however, the location of the fœtal inclusion is probably acquired secondarily in consequence of changes occurring during development, as in the case of sacral teratomata on the ventral aspect of the sacrococcygeal region in which the anlage was

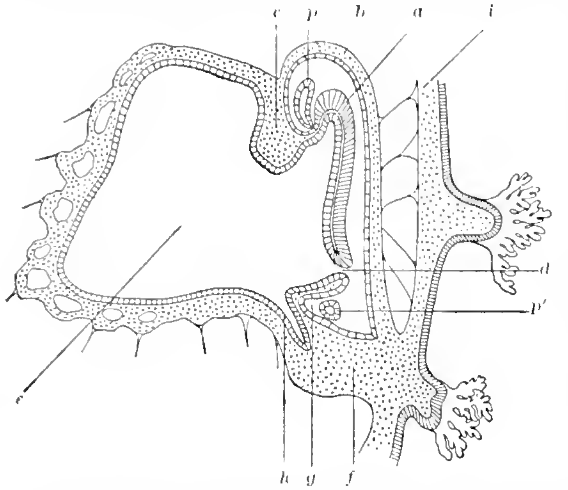

FIG. 4675.—Schematic Representation of Relations of Parasitic Anlage in Epignathus (*p*) and Sacral Teratoma (*p'*), based on sagittal section of Spee's early human embryo. *a*, Neural plate; *b*, amnion; *c*, heart area; *d*, neurenteric canal; *e*, umbilical vesicle; *f*, belly-stalk; *g*, region of anal membrane; *h*, allantoic duct; *i*, chorion. (After Marchand.)

primarily attached in the vicinity of the hind-gut and carried ventrally by the flexure of the autositic axis.

In contrast to the primary independence of the nutritive apparatus of both embryos in the case of parasites arising from symmetrical double monsters, the rudimentary anlages producing true fœtal parasites present little evidence of having had separate chorionic attachments. It is doubtful whether such parasites ever possess rudiments of true umbilical cords or allantoic attachments, notwithstanding their reported presence in certain cases.

In attempting to arrive at some conclusion regarding the vexed question concerning the origin of the rudimentary anlage producing the parasite, it may be assumed that the latter represents the development of a germ-cell or cell mass that progresses independently in the earliest stages, although later dependent for its nutrition upon the autosite. Reviewing the established facts relating to the origin and early changes of the ovum leading to the formation of the blastoderm from which the embryo proceeds, two possible sources of the rudimentary anlage may be suggested that are not incompatible with the known facts of embryology. These are: (1) that the rudimentary anlage may be the product of the imperfect development of a fertilized polar body; (2) that the parasite may arise from the differentiation of a special or an isolated group of segmentation cells.

The significance of the polar bodies as abortive or rudimentary ova, liberated during the process of maturation of the female sexual cell, is admitted by all. These rudimentary ova, the polar bodies, contain the same morphological constituents and therefore the same potentialities as the larger matured oöcyte, only in diminished force. Usually the polar bodies remain for a time beneath the egg envelope, or zona pellucida, closely related to the early segmentation spheres, later disappearing.

Since the occurrence of segmentation and formation of the blastoderm in vertebrates implies the development of a fertilized ovum—a true parthenogenetic development not occurring among the vertebrated animals—it is of interest to note that in addition to the direct observations of Platner and of Kostanecki on the fertilization of the polar bodies of lower forms, the older observations of Bischoff, proving that in the segmenting ovum of mammals (rabbit, dog) the living spermatozoa may exist beneath the zona pellucida in the vicinity of the polar bodies, have been confirmed by Assheton[84] and by Bonnet.[85] In view of these investigations it is highly probable, at least not improbable, that in exceptional cases the polar body may undergo fertilization and enter upon a development which may produce a small blastodermic vesicle and rudimentary anlage capable of giving rise to the parasite. The anlage so arising lies closely related to the blastoderm developed from larger egg. When that derived from the polar body retains the usual primary relations of the latter it will lie in proximity to the first plane of cleavage, which corresponds with the later axis of the embryo as established by the notochord and the medullary furrow. Since the last-named structure becomes the neural tube, it is evident that the rudimentary anlage may become attached in the vicinity of the medullary folds and be drawn within the larger embryo to become an encranius. It is, however, well established that the polar body may lie in relation to other portions of the segmenting mass and hence become attached to various parts of the larger anlage. When related to the ventrally approximating somatopleuric folds, the rudimentary anlage may be enclosed within the later abdominal walls or carried into the body cavity to form an inclusion.

The possibility of the rudimentary anlage being early included between the segmentation cells of the larger anlage has been shown by the observation of Assheton on the rabbit in which the polar body was found between the blastomeres. Assuming that the ferilized polar body suffers such displacement it follows that the resulting rudimentary anlage may obtain later an intramesoblastic position and may become an inclusion in some deeply seated organ, including the sexual glands. In such manner the existence of the ovarian dermoids and the teratomata of the testicle find a plausible explanation.

The important fact that the embryonoid growths of the sexual glands consist of derivates of all three germ layers was emphasized by Wilms in the papers already quoted. Other investigators, including Pfannenstiel, Krömer, Mertens, Arnsperger, Franzen, and Emanuel, have confirmed these views, which may be regarded as established. Bandler,[86] however, challenges these conclusions and denies that the entoblastic derivatives take part in the formation of these growths, the origin of which he attributes to possible cell dislocations occurring during the complex development of the Wolffian body, kidney, and sexual glands. The formation of such growths implies development of a sexual cell. The necessity of accounting for such process has led to many theories as to the possibilty of development proceeding from sexual cells within the ovary and testicle without the influence of the male element. The well-known existence of parthenogenic development among certain invertebrates suggested the possibility of the occurrence of a similar process in the higher animals; parthenogenesis, therefore, has been accepted as an explanation of the congenital tumors of the sexual glands by many authors, some going to such length that they accept the radical proposition that the sexual cells within the testicle are capable of producing the teratomes of that organ. Additional support for such views has been claimed from the interesting experiments with unimpregnated eggs of certain invertebrates which under particular conditions undergo cleavage and attempt the earlier phases of development. Somewhat analogous changes have been observed in the ova of vertebrates resulting in an imperfect segmentation, or more accurately "fragmentation." The conclusion of Bonnet,[87] that there is no justification for assuming the occurrence of parthenogenesis among the vertebrates, may be accepted as a reliable verdict founded upon an exhaustive and critical review of the evidence presented by the literature of this interesting problem.

Beard[88] has suggested an explanation of the congenital tumors of the sexual glands, as well as of other regions, based upon his investigations on the early embryos of the skate. In these he found that particular blastomeres are very early set apart for the formation of the sexual cells of the embryo and take no part in its general development. The descendants of these special *primary germ-cells* constitute the sexual elements of the ovary and the testicle. Beard regards the embryonal tumors as derived from aberrant members of this group of primary germ-cells, which differ from the generations of secondary germ-cells, represented by the ova and the spermatozoa, in not having undergone the cytological changes incident to maturation, extrusion of the polar bodies, and reduction of chromosomes. The primitive germ-cell, as Beard regards it, is the sister, not the derivative, of the embryo, and therefore capable of giving rise to a rudimentary twin — the included parasite or embryoma. As Beard admits, he establishes only the existence of the vagrant primary germ-cells and does not explain their spontaneous development. He regards these cells, however, as endowed with an inherent potentiality which may institute independent formative processes, so that "neither a congregation of germ-cells nor a parthenogenetic development of such is needed to account for dermoids."

A possible source of the rudimentary anlage producing the parasite has been suggested by the interesting experiments relating to the development of separated segmentation spheres, carried out by various investigators during the last decade. The observations of Driesch, Born, Wilson, Morgan, O. Hertwig, O. Schultze, Herlitzka, and others, have shown that artificially separated segmentation spheres may develop into perfect although small embryos, the size, within certain limits, being determined by the proportionate value of the isolated cells to the entire segmentation mass. The observations of Roux [69] upon young frog larvæ seem to warrant the assumption that groups of segmentation cells may become disconnected and displaced and finally enclosed within the derivatives of the blastodermic layers. Bonnet assumes, and with reason, that such inclusions may later undergo further differentiation and become congenital fœtal growths. Coley and Buxton conclude, after reviewing the various theories, that the separation of segmentation cells offers the most satisfactory explanation.

There are, therefore, two plausible sources for the rudimentary anlage producing the parasite, the one being the fertilization of an abortive ovum (the polar body), the other the tardy differentiation of a group of vagrant segmentation cells. There seems no reason for regarding either of these possibilities as the exclusive mode of production, and it may be assumed with probability that both methods may contribute to the various types of parasitic duplicity. The observed attempts, in certain instances, at the formation of imperfect fœtal membranes may be related, possibly, with an origin from a fertilized polar body, the development of which abortive ovum would be more favorable to the formation of such structures than that of included segmentation spheres.

The foregoing considerations emphasize the common origin of cystic dermoids and teratomes of the sexual glands and of other fœtal inclusions, the sharp lines drawn by Wilms being justly regarded by Marchand and by Bonnet as unwarranted.

The causes determining the period at which the fœtal inclusion shall develop within the surrounding tissue remain unknown. In general it may be assumed that conditions affecting nutrition and tissue activity are responsible. The fact that the ovarian inclusions usually develop during the period of sexual activity may be attributed to the stimulus incidental to the well-known periodical congestion of the ovary and associated parts. On the contrary, the fact that teratomata of the testicle are more frequently encountered in young subjects may be connected with the more favorable conditions of active nutrition presented by the young organ than during the later years where the imprisoned anlage suffers compression and arrest.

Malformation of the Organs.

The malformations described in the foregoing pages are the expression of influences affecting more or less profoundly the entire organism; it remains briefly to discuss the more limited developmental defects that are encountered in the individual organs.

Defects of the Cerebro-Spinal Axis.—The early appearance, exposed position, and delicate walls of the neural tube render it especially liable to unfavorable influences affecting its growth which result in malformations of the spinal cord and brain and their membranous and bony envelopes.

It will be recalled that the cerebro-spinal nervous axis is the direct transformation of the neural tube, the latter first appearing as a groove along the dorsal surface of the early embryo. The ectodermal medullary folds bounding the intervening neural groove approach and gradually convert the furrow into the neural tube, the expanded cephalic segments of which form the brain vesicles. Following the closure of the neural tube by fusion of the medullary folds, the surface ectoderm becomes separated from that lining of the neural tube by the ingrowth of the surrounding mesoderm. The latter subsequently undergoes differentiation into the meninges and the vertebral column and brain case. Each segment of the spine, consisting of a body and a pair of neural arches, is developed within the mesoblast, supplied by the somites as the skleratome, from three chief centres. The latter are: one for the body and one on each side for the corresponding half of the arch. Failure of the arches to unite dorsally in the midline may result in a more or less conspicuous cleft associated with developmental disturbances of the spinal cord and its membranes.

Defects Caused by Imperfect Closure of the Spinal Canal.—Clefts of the vertebral canal may be divided according to their relations with the exterior into two chief groups, *open* and *covered*. The former, termed *rachischisis*, present an open furrow-like defect at the bottom of which may be seen the vertebral bodies. The covered clefts are distinguished by the presence of a more or less prominent sac, hence the names *spina bifida cystica*, or *rachischisis cystica*, by which this group is properly known, although the less specific term *spina bifida* is often used instead. Both forms of cleft may occur in any part of the spine, and may be limited or very extensive.

Rachischisis.—The deformity included under this name is due to faulty development and imperfect union of the neural arches. When well marked it appears as a widely open groove bounded by rudimentary processes on each side representing the imperfectly formed arches. The skin being absent, the vertebral bodies are covered by the dura and the ventral portion of the pia, with, perhaps, remains of the atrophic spinal cord and the associated nerves. The cleft may involve the entire canal (*holorachischisis*), and is then frequently associated with an analogous defect of the skull; or it may be limited to one part of the spine (*merorachischisis*). The usual seat of the latter defect is the lumbo-sacral region, although clefts in the cervical portion of the spine occasionally occur. The intervening thoracic region is seldom involved. Rachischisis is usually attended with spinal curvature; the total and cervical clefts are associated with lordosis and those of the lower segment with kyphosis. In the latter cases, other profound defects of the ventral body wall, as eventration or ectopia of the bladder, are often also present.

Viewed from behind, the centre of the defect is occupied by a soft red membrane; this represents the flatly expanded pia enclosing the remains of the rudimentary spinal cord which has succeeded the unclosed neural tube. When the rachischisis is total, the cord is practically absent (*amyelus*); when less extensive, the cord may be present as a plate-like strip of loose, highly vascular tissue fused with the pia. This mass, the *area medullo-vasculosa*, may form a continuous structure, or be broken up into a delicate veil-like tissue. Remains of nerve cells and nerve fibres may be recognizable. At its margin the central area becomes continuous with the surrounding integument, the epidermis of the latter extending for a variable distance upon the pia. This boundary ring is

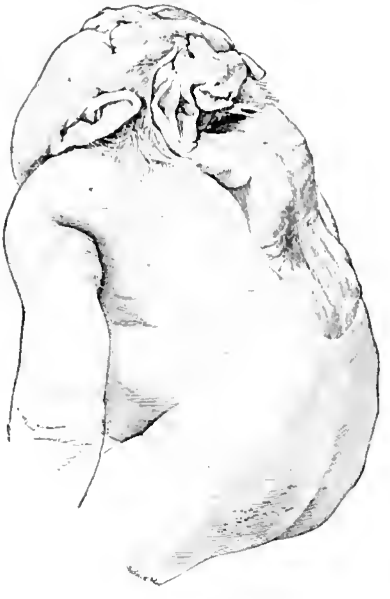

FIG. 4676.—Cranio-rachischisis with Absence of Brain and Spinal Cord. (Ziegler.)

termed the *zona epithelioserosa*, outside of which lies the *zona dermatica*, as the thicker margin of the surrounding integument is called.

The ventral relations of the meninges are more normally preserved, the anterior part of the subarachnoidal space being represented by the cleft between the pia and the subjacent arachnoid attached to the dura. This space sometimes becomes distended by accumulation of fluid. The rudimentary spinal nerves are attached to the ventral surface of the vascular membrane and may at times be followed into the atrophic nervous mass. In rare cases the vertebral bodies themselves may be imperfect and cleft, thereby giving rise to *rachischisis anterior*.

Spina Bifida Cystica.—The covered forms of spinal cleft are distinguished by the presence of a cyst, which protrudes through the fissure in the spine, and is externally evident as a saccular protrusion of variable size. Depending upon the structures involved, these defects are divided into three chief groups: (1) *myelomeningocele*, in which both the spinal cord and its membranes are included within the sac; (2) *meningocele*, in which only the spinal membranes compose the cyst; (3) *myelocystocele*, in which the spinal cord itself undergoes dilatation.

Myelomeningocele of the lumbo-sacral region is the most common form of spina bifida; much more rarely are the cervical and thoracic segments of the spine the seat of this defect. In rare cases the entire sacral region may be involved. Usually a rounded tumor, varying in size from a nut to an apple, appears in the midline about the juncture of the lumbar and sacral regions. When the child survives, it gradually increases and may attain the dimensions of a child's head.

The tumor is fluctuating, tense, and elastic, and often overhangs the lower margin of the cleft. When entirely covered by skin, the latter is attenuated and frequently cicatricial in appearance. More usually, however, the most prominent surface of the tumor is wanting in integument and invested by a smooth, soft, vascular membrane which is separated from the surrounding and elevated skin by a sharply defined boundary zone, covered with epidermis, and of a pale or bluish tint. The central part, uncovered by skin, is usually somewhat sunken and corresponds to the *area medullovasculosa;* the *zona epithelioserosa* and *zona dermatica* mark the intermediate and outer tracts of the tumor respectively. Pressure during labor, or the increasing tension following growth, may affect the nutrition of the integument and give rise to ulceration or gangrene, which results in perforation, destruction of the sac, or secondary cicatrices.

The defects of the skeleton include arrested development of the spinous processes and adjacent parts of the neural arches, the deficiency being most marked in the vertebræ contributing the lateral boundaries of the cleft. The latter may be limited to two, or even a single lumbar vertebræ; usually it involves the upper part of the sacrum, and may extend as far as the sacral fissure.

The spinal cord is commonly bent strongly backward and attached to the middle or upper part of the sac, the associated spinal nerves being correspondingly displaced. When the fissure lies near the lower end of the spine, the extremity of the cord may be drawn entirely into the sac, ending possibly in a flat expansion and without a conus. In many cases the cord extends lower in the spinal canal than normal. The pial investment is complete, and, in conjunction with the arachnoid, forms the sac enclosing the spinal cord; the dura, due to its imperfect development in association with the defective vertebræ, is always absent over the most prominent part of the tumor. In the much rarer and usually smaller thoracic and cervical examples of myelomeningocele, the spinal cord commonly protrudes less from the vertebral canal, being attached to the sac by a band-like fold. In exceptional instances the sac may escape through a ventral fissure, then constituting the rare defect *myelomeningocele anterior*.

Meningocele, in which the cyst is formed by the spinal membranes alone, occurs less frequently than sometimes assumed, since ordinarily the protruding membranes are closely associated with displaced nervous tissues. Uncomplicated spinal meningocele is encountered almost always at the lower end of the spine, the defects at the upper end of the column existing commonly in conjunction with hernia of the brain membranes.

The opening through which the meninges escape is not necessarily a posterior median cleft, since the sac may at times protrude between the arches, or through the intervertebral foramina or the sacral canal; rarely imperfections of the vertebral bodies allow the escape of the membranes anteriorly.

The sac of the meningocele appears oftener at the side, or downward, than in the midline. Since this defect is less unfavorable to prolonged life, the tumor not infrequently attains considerable dimension, at times increasing from the size of a hazelnut at birth to that of a man's head. The fluctuating cyst, filled with clear fluid, is covered with integument that may differ little from that of the surrounding parts; in other cases it may be tense and even gangrenous and rupture when subjected to unusual pressure. The wall of the sac consists principally of the abnormally distended arachnoidal supplemented by an imperfect dural layer which blends with the integument. The cavity of the cyst presents a smooth inner surface and communicates with the spinal subarachnoidal space; it is sometimes traversed by one or more spinal nerves, which otherwise run in the cyst wall, and may be secondarily subdivided into several compartments.

Myelocystocele or *syringomyelocele* implies a local dilatation of the central canal of the spinal cord, in consequence of which a larger or smaller segment of the cord, with the surrounding pia and arachnoid, becomes converted into a cystic tumor. The dura does not extend beyond the spinal canal. Since the sac represents the enormously dilated central canal, its lining consists of the ependyma cells and is, therefore, a layer of cylindrical epithelium. The remains of the compressed and atrophic nervous matter are seen on the ventral wall of the cyst as an area medullovasculosa to which rudimentary nerve roots may at times be traced.

Myelocystocele is often associated with lateral fissures and asymmetrical defects of the spine, especially shortening of the trunk. It may occur in any region, and is sometimes connected with anterior vertebral clefts.

When the dilatation of the cord is associated with distention of its membranes, the condition is termed *myelocystomeningocele*, a defect that may, when extensive, be mistaken for myelomeningocele. The differential diagnosis can be made by observing the character of the lining of the cyst, cylindrical cells being never found unless the sac is derived from the central canal of the cord.

Spina bifida occulta is the term applied to cases in which neither a cleft nor cystic tumor is externally visible. Such masked defects are usually of small extent and of sacral or lumbo-sacral origin. The position of these hidden imperfections is often indicated by a somewhat depressed or cicatricial area, or by a small cutaneous tumor. In other cases an unusual tuft of hair alone marks the location of the deeply seated defect, which on pressure may be detected as a minute opening in one or more vertebræ. In the cases carefully studied the greatly elongated spinal cord extended into the sacral canal and was connected with the external soft parts by a fibrolipomatous mass. The spinal canal may, however, be dilated by the presence of such tumor, and the nerve roots forming the cauda equina may be unfavorably affected, resulting in considerable motor and sensory disturbance in one or both lower extremities. Paralytic club-foot and derangement of the functions of the bladder are among the consequences of these defects of the neural canal and its contents.

Doubling of the spinal cord (*diastematomyelia*) is an occasional accompaniment in rachischisis, more rarely in myelomeningocele; the duplicity consists in the cleavage of the immature cord, which is then represented by two usually atrophic or rudimentary bands, seldom by nervous cords of more perfect development. The presence of a thorn-like spur or process in certain cases suggests that the doubling of the cord may sometimes depend upon mechanical disturbance.

The *genesis* of spina bifida was formerly regarded as closely related to an accumulation of fluid within the spinal canal leading to rupture of the distended sac. Such origin of the defects under consideration is now generally considered untenable. The present views, however, are far from settled. According to v. Recklinghausen, whose classic investigations have greatly advanced our understanding of spinal clefts, the defective median union is occasioned by inadequate development, or aplasia, of the spine, due to deficient growth of the blastoderm as a primary cause. The observations of Tourneux and Martin, on the other hand, point to an incomplete separation between the medullary folds and the adjacent ectoderms as the immediate factor, in consequence of which the lips of the neural groove never become united. The surrounding mesoblastic tissue, the skleratome, in which the vertebræ develop, fails to produce arches which unite. Ziegler inclines to the view that the defective or arrested development is due to a "primary agenesis" affecting the germ, regarding the symmetry of the malformation as evidence opposed to the assumption of mechanical impressions from without. The marked differences in these defects as to the extent, situation, and details suggest the probability that their mode of production is by no means always the same. In complete rachischisis the rudimentary condition and incomplete separation of the medullary folds which preclude the closure of the neural groove not unlikely are associated with abnormality or excessive narrowness of the amniotic sac, whereby the arrested growth and nonunion of the medullary folds are favored. The explanation of the favorite location of myelomeningocele in the lumbo-sacral region is found in the fact that this part of the spine not only corresponds to the area in which closure of the neural canal is longest delayed, but is also subject to the disturbing influence of a too closely applied amnion, on account of the flexure which here is more pronounced than in the thoracic segment. The upper cervical region, occasionally the seat of spina bifida, is also involved in the marked flexure at the cephalo-cervical juncture. The observations of v. Recklinghausen have established the fact that in many cases, the length of the spinal cord is relatively excessive, a condition favorable to the production of kinks which at the points of least resistance may become additional factors in causing protrusion of the cord and its membranes. Hertwig, basing his conclusions on experimental studies on frog's ova, regards spina bifida as indicative of faulty closure of the blastopore, ascribing the arrest of development to influences which very early affect the germ-mass. That this malformation may arise apart from mechanical disturbance due to the amnion is shown by its occurrence in the *anamnia* (fishes and amphibians) in which fœtal membranes are never formed.

Defects due to Arrested Development of the Cranial Vault.—The defective formation of the vault of the skull presents a series of malformations which affect not only the brain case, but also the enclosed nervous mass. Since the arrest of development involves those parts of the skull which are analogous to the neural arches of the vertebræ, these malformations of the skull may be appropriately termed *cranioschisis*, of which two chief groups—*acranius* and *hemicranius*—are recognized; these depend upon the degree of the defect, and vary from total absence of the vault to partial arrest of development. The associated defective conditions of the brain mass include *anencephalus*, *exencephalus*, and *cephalocele*.

Acranius.—This malformation is distinguished by very slight or totally deficient development of the bones comprising the cranial vault, resulting in a skull in which the base is often the only part present. The brain shares in the defective development and is frequently wholly lacking, or at best represented by rudiments of nervous substance contained within a richly vascular spongy mass of connective tissue which forms a membranous covering for the base of the skull. This structure, the *area cerebrovasculosa*, corresponds to the area medullovasculosa already noted in connection with the defects of the spine, and consists of the remains of the pia and the nervous tissue.

Hemicrania implies a partial development of the vault bones, which, although producing more of the skull than present in acrania, results in an imperfect closure, principally in the posterior segment. This condition is often attended with protrusion of the brain substance (*exenceph-alus*) which may rise above the imperfect skull as a crowning mass or form a pendulous sac-like tumor over the occipital region. The protruding brain, although commonly uncovered by integument, is invested by a soft and yielding membrane representing the pia and arachnoid.

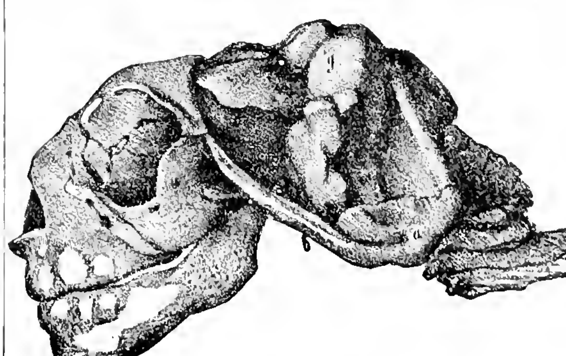

Fig. 4677.—Acranus Exencephalus. (Vrolik.)

The defective development resulting in cranioschisis frequently affects also the adjacent cervical vertebræ, thereby giving rise to the condition known as *craniorachischisis*, in which a cleft extends from the posterior part of the skull onto the upper part of the spine. The lordosis following the shortening and distortion of the vertebræ markedly influences the position of the head, the occiput being bent backward and the face thrown upward. This, in conjunction with the flattened cranial vault, deficient brows, and the consequent seemingly excessive protrusion of the eyes, gives to these malformations the peculiar appearance described as "toad-headed."

Cephalocele.—Associated with partial defects of the skull, but antedating the bony deficiencies, protrusions of the cranial contents may occur as various forms of cerebral hernia. The fallacy of regarding cephalocele as secondary to and dependent upon the defect in the brain case is suggested when we recall the time (end of the third month) at which ossification begins—a date manifestly too late for the production of changes so profoundly affecting the brain. The tumor escaping through the limited area of defective skull may consist of brain substance, only of its membranes, or of both. When composed of brain substance, the hernia is termed *encephalocele; hydrencephalocele*, or *hydrocephalus*, implies an accumulation of fluid within the ventricles and a more or less extensive prolapse of the dilated brain. Should, however, the accumulation of fluid take place after the development of the skull has well progressed, the condition may result in the general enlargement of the cranium, with the attendant alteration in the brain, seen in congenital hydrocephalus. The excessive production of the intraventricular fluid, which may reach a litre in quantity, takes place from the choroidal plexus, the lateral and third ventricles especially undergoing marked dilatation, while the surrounding nervous substance usually suffers greatly. The cranial vault shares in the expansion and becomes excessively thin, the fontanels being abnormally large and the sutures wide and ununited. When the hernia contains only the distended arachnoid and pia the condition is known as *meningocele*, or *hydromeningocele*. In case the brain substance is at the same time involved, as frequently it is, *meningo-encephalocele* is the appropriate designation for such deformity.

The most frequent seats for cerebral herniæ are the occipital region immediately above the foramen magnum and the vicinity of the root of the nose. The seats of the herniæ are indicated in the forms variously described as naso-frontal, naso-ethmoidal, naso-orbital, or, exceptionally when at the base or side of the skull, as spheno-pharyngeal, spheno-orbital, spheno-maxillary or lateral.

Iniencephalus.—In rare instances the cranial defect includes a combination of hydrencephalus and encephalocele with fissure of the adjoining cervical vertebræ. The distended occipital tumor overhangs the spine, the encephalocele being received in the vertebral cleft and the integument of the head, passing directly into that of the back.

Microcephalus and Micrencephalus.—These conditions, distinguished by abnormal smallness of the cranium and the enclosed brain, represent defective development of the nervous mass, the arrested growth of the latter probably preceding, not following, that of the skeleton. In contrast to the etymological comprehensiveness of the term, as including all forms of diminished head, microcephalus, as at present understood, implies the associated presence of a brain which, with the exception of its abnormally small size, may not be materially deformed. Further, that the diminished brain case is part of a body of usual stature, thus excluding the microcephalus seen in dwarfs (*nanocephalus*).

The decrease in the microcephalic skull affects especially the cranium, the facial portion often suffering but little arrest in its development. Assuming the average cranial capacity as 1,500 and 1,300 c.c. and the average horizontal circumference as 52 and 50 cm., for the adult male and female skull respectively, in extreme cases of microcephalus the cranial capacity may be diminished to little more than one-fourth of the normal, and the circumference may reach only two-thirds of the normal measurement. The unusual closeness, although not necessarily disappearance, of the sutures and the absence of the fontanels are among the characteristic features of the young microcephalic skull, the cranial vault, both in its sagittal and frontal curvature, being decidedly diminished. In consequence of the slight involvement of the face the narrowing of the cranium becomes conspicuous and confers upon the microcephalus a simian type, since the skull seemingly possesses a median crest. An additional peculiarity is also seen in the forward bend of the outer surface of the occipital bone, the external protuberance apparently being displaced upward. The partial or complete obliteration of the cranial sutures, upon which much emphasis was formerly laid, is far from constant, since synostosis in young microcephalic skulls is unusual, such crania even in later life occasionally exhibiting persistent sutures. Union of the sagittal suture, however, is not infrequent; since arrested growth of the brain occurs early, the elongation of the skull usually associated with such synostosis is not observed.

The *micrencephalus* associated with the diminished cranial capacity presents wide variations of brain weight (from 200 to 800 gm.), the loss being chiefly due to that suffered by the cerebral hemispheres, although usually the cerebellum is also under the normal weight. While in micrencephalus of low degrees the fissures and convolutions are practically normal, in the higher forms the frontal, parietal, and occipital lobes may be greatly distorted and disturbed. Often along with simplification of the gyri unusual prominence and partial exposure of the central lobe, or island of Reil, are highly characteristic in the more marked grades of micrencephalus.

Malformations of the brain, depending upon arrested development, affect chiefly the cerebral hemispheres, since these represent the more highly specialized portions of the encephalon, although the cerebellum and the brain stem are at times also involved. The defects of the cerebrum include irregularities, simplification, and suppression of the convolutions, imperfect development of the olfactory lobes, corpus callosum, basal nuclei, and other parts derived from the subdivisions of the primary anterior cerebral vesicle. The lateral and third ventricles sometimes become the seat of abnormal accumulations of cerebro-spinal fluid, followed by distention and more or less unfavorable change in the surrounding parts. To such congenital defects, when not sufficiently grave immediately to endanger life, although always productive of impaired intellect, the term *porencephalus* has been applied as distinctive from hydromicrencephalus, in which the defective features are more exaggerated. The former condition may be associated with extensive involvement of the adjacent frontal and parietal lobes, the affected convolutions and fissures presenting a characteristic radial disposition. In consequence of the impairment of the cortical motor areas contractions and atrophy of the limbs of the opposite side are frequently observed.

Cyclocephalus.—A conspicuous group of defects involving the great brain, eyes, and nose is derived from arrested development of the primary anterior cerebral vesicle. It will be recalled that the latter soon subdivides into forebrain (prosencephalon) and interbrain (thalamencephalon), from which are subsequently developed the cerebral hemispheres, including the lateral and third ventricles and the parts surrounding these spaces. The early outgrowth of the eye sacs from the posterior segment of the primary cerebral vesicle is closely connected with the changes which the latter undergoes. Arrest of development of the primary brain sac, when profound, may prevent the secondary longitudinal subdivision of the forebrain into the two cerebral hemispheres, the latter in extreme cases being represented by a single sac which may occupy a large part of the cranial space and be filled with fluid. When less aggravated and of low degree, the defective development may find expression only in particular parts, as the olfactory region, the anterior convolutions, the corpus callosum, the optic thalamus, etc. Those derived from the middle and posterior primary cerebral vesicles, as the corpora quadrigemina and the parts surrounding the fourth ventricle, are usually little disturbed.

The failure of the cerebral hemispheres to develop, hence apparently to fuse, exerts a profound influence on the relation of the optic vesicles, since instead of being widely separated as in the normal condition, they may become closely approximated or blended and lead to the formation of a single visual organ, this condition constituting *synophthalmus* or *cyclopia*.

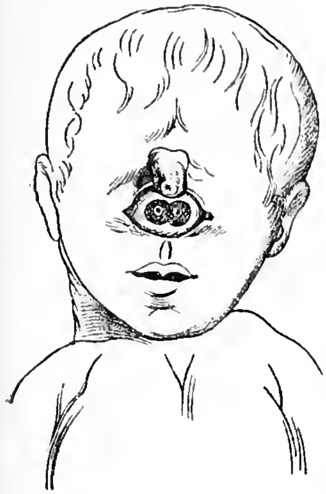

FIG. 4678.—Synophthalmus. (Heyman.)

Since the frontonasal process, which takes an important part in the formation of the external nose, shares in the general defective development of the forebrain, malformations of the nose are usually associated with synophthalmus. The typical cyclopian monster is distinguished by a single eye within a single orbit, occupying the middle of the face. A true nose is wanting, but about the orbit protrudes a fleshy proboscis provided at its end with a single or double opening. Depending upon the extent of developmental arrest, transitional forms of all degrees exist. Beginning with the slightest, in which an unusually narrow face, closely set eyes, and a rudimentary, although normally situated nose are the chief features, the relations of the eyes become progressively more intimate until, in marked instances, they lie within the fused orbits side by side, the rudimentary nose having been replaced by a proboscis above the orbital opening. The two eyes may be represented by a single ball of unusual size, in which double or partially blended corneæ, pupils, lenses, and optic nerves are present. When synophthalmus of high degree exists, the fusion of the two optic organs and nerves may be complete.

Since the normal union of the fronto-labial and maxillary processes (which plays an important rôle in the formation of the face and upper oral boundaries) may be hindered by the same influences that produce cyclencephalus, it is not unusual to find clefts of the lip and palate associated with the characteristic deformities of a well-marked cyclops. Likewise disturbed relations in the position of the visceral arches may result in coincident deformity of the external ear, the fusion of which constitutes *synotus* or *cyclotus*. In extreme cases, in addition to disappearance of the nose (*arhinencephalus*) as well as proboscis, the oral aperture may also become closed (*cyclostomus*) by fusion of the displaced visceral bars. When only feeble development is conjoined with fusion of the optic vesicles, the resulting organ may be so imperfect that a distinct eye is absent (*anophthalmus*), or at best represented by an extremely rudimentary organ occupying a slight central depression.

Coincident with cyclencephalus of high degree, defects involving the parts adjacent to the orbital, nasal, and oral cavities are not infrequent. Such malformations may include imperfections or absence of the ethmoid bone and nasal septum and cleavage of the palate and upper lips; less commonly the inferior boundary of the oral opening may be deficient.

Malformations of the Eye.—In addition to the foregoing conspicuous changes (cyclopia) in the position and development of the visual organs associated with the grave general arrest affecting the development of the anterior brain vesicles, the eye may be the seat of local defects, the more important of which may conveniently be briefly noted in this place.

Retention of fœtal structures and conditions which usually disappear before birth account for some of the slighter anomalies, including persistence of the pupillary membrane in the form of vascular fringes attached to the free edge of the iris; persistence of the remains of the hyaloid artery, as a fibrous cord stretching from the optic papilla toward the posterior surface of the lens; coloboma of the iris and of the choroid, as well as cysts connected with the eyeball and containing portions of its contents, are referable to imperfect closure of the fœtal choroidal fissure.

When the developmental arrest has been more general, the entire organ remains undersized (*microphthalmus*) and retains many features of its fœtal condition, as shown by the unusually large lens, which may occupy the greater part of the eyeball, the persistence of the vascular primary vitreous tissue and remains of the hyaloid artery. The retina is often imperfect and the effects of an unclosed choroidal fissure are seen in coloboma of the iris and choroid. The small eyeball is enclosed by a relatively thick sclerotic coat and diminutive, illy defined and often untransparent cornea. Microphthalmus may be unilateral or bilateral and associated with impaired development of the skull and brain.

Anophthalmus, or total absence of the eyeball, represents the extreme condition of an arrested development which fails to produce even a rudimentary organ within the small and imperfect orbit. This condition may exist on one or both sides.

The eyelids also share in the defective development, and may enclose a palpebral fissure of abnormal narrowness (*ankyloblepharon*), often seen in conjunction with microphthalmus. The fissure may be wanting (*cryptophthalmus*), owing to fusion of the lids, or the latter may be congenitally adherent to the eyeball (*symblepharon*). *Epicanthus* is distinguished by the presence of a cutaneous fold, occupying the inner canthus to a variable extent, attributable to the persistence of the plica semilunaris to a degree corresponding to the nictitating membrane of lower forms.

MALFORMATIONS OF THE FACE AND NECK.—Since these malformations result largely from arrested or defective union of the visceral arches with one another and with the surrounding parts, a brief outline of the normal development will be a useful preface to the description of the defects in question.

The face and neck are primarily formed by the fusion of a paired series of lateral bars, the *visceral arches*, with one another and the unpaired median *frontal process*, the downward prolongation of the region of the forebrain. The visceral arches in man and mammals for a time are separated by *external* and *internal furrows*, the representatives of the slit-like apertures, or *branchial clefts*, of the lower forms (fishes). The median ends of the first pair of visceral arches are subdivided into a short upper or *maxillary*, and a longer lower or *mandibular process*, between which and the frontal process the primary oral cavity is included. With the appearance of the nasal pits the frontal process differentiates into the median *naso-labial* and the *external nasal process*, lying respectively between and outside the olfactory depressions. The lateral angle of the naso-labial process thickens and becomes the *internal nasal* or *globular process*, which on each side

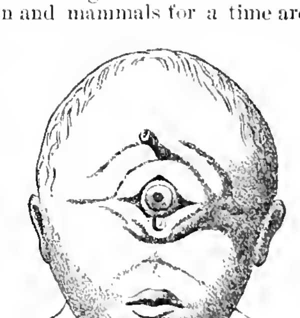

FIG. 4679.—Synophthalmus Cyclopia. (Jourdan.)

bounds the olfactory pit. The further differentiation of the fronto-nasal and inner nasal processes gives rise to the nasal septum and inner boundaries of the nasal apertures and the *nasal groove*, the latter marking the line of fusion between the maxillary and internal nasal processes. The external nasal processes contribute the cartilages and the lateral boundaries of the front of the nasal fossæ. These processes, in conjunction with the adjacent maxillary divisions of the fourth visceral arch, also bound the *lachrymal groove* leading from the eye to the nasal furrow. Fusion of the adjacent portions of the fronto-nasal process with the maxillary bars gives rise to the cheeks and superior oral boundary, the latter differentiating into the upper lip and the superior and intermaxillary alveolar borders. The widely open recess which for a time constitutes the primary oral cavity becomes divided into a respiratory and an alimentary part by the formation of a septum formed by the union of the palatal plates differentiated from the maxillary processes. The palatal shelf thus formed unites with the nasal septum to compensate the closure of the nasal fossæ. The external visceral furrows, with the exception of the first which persists as the external auditory canal, are obliterated by the approximation and fusion of the arches. The internal furrows, or *pharyngeal pouches*, likewise disappear; the first, however, is converted into the Eustachian tube, and secondarily is associated with the tympanic cavity. The entoblastic lining of the third and fourth pouches gives rise to the epithelial anlages of the thymus and thyroid bodies respectively. The inner ends of the second arches contribute a V shaped area, from which the posterior third of the tongue is formed, the anterior two-thirds of the organ being derived from an unpaired elevation, or tuberculum impar, which arises in front of the junction of the second arches.

Facial Clefts.—From the foregoing it is evident that such defects may arise as the result of *primary* arrest of

FIG. 4680. Facial Clefts. (Ross.)

development and union of the embryonal processes, or that they may follow *secondary* disturbances affecting parts already partially formed.

Aprosopus is the most pronounced degree of such primary malformations, and implies an early and complete arrest of development of the parts normally concerned in forming the face. The latter in this condition is practically absent and replaced by a widely open, irregular oral recess.

Clefts of the Lip, Jaw, and Palate.—Usually the primary defective development is less general and limited to faulty union between the processes concerned in forming the upper and lateral parts of the face. The clefts follow the lines of primary union, and may involve (1) the upper lip alone (*cheiloschisis*), (2) the lip and maxilla (*cheilo-gnathoschisis*), (3) the lip, maxilla, and palate (*cheilo-gnatho-uranoschisis*).

Simple cleft lip, or *harelip*, is usually lateral (very rarely median) and on one side only. The fissure follows the line of the nasal groove between the globular and maxillary processes, extending when complete from the inner border of the nasal aperture to the mouth. Subsequent union may reduce the defect to a mere prenatal scar.

The *labio-maxillary clefts* involve the upper jaw as well as the lip, the line of bony separation extending either between the canine and lateral incisor tooth, or, as is most frequently the case, between the lateral and the central incisor. In not a few cases a supernumerary incisor tooth, or sometimes teeth, is present, the cleft then usually passing between the second and third. The defect may be unilateral or double, and the relations to the teeth symmetrical or unlike on the two sides. As emphasized by Marchand, the early stage at which the faulty union is established anticipates the differentiation of the maxilla and the intermaxillary bones, as well as the appearance of the dental buds locating the milk teeth. These facts, together with the possible variations in the relation of the teeth germs to the bony segments later blended to form the upper jaw, detract from the assumed importance of these malformations as evidence in determining the mooted existence of double intermaxillary bones on each side. Symmetrical cleavage involving only the lip and jaw, the intermaxillæ standing out as an isolated process between the lateral fissures, are rare, the labio-maxillary clefts being usually combined with some form of palatal fissure.

Such defects, involving the palate as well as the lip and superior maxillary bone, include two groups, the *median* and the *lateral*. The former, in which a wide median cleft of the lip and jaw is continuous with an extensive central deficiency of the palate, is usually associated with malformation of the fore end of the brain-case, as seen in cyclencephalus, the facial defect being an expression of the same profound developmental arrest that is responsible for the cerebral deformity.

The second and more usual type is distinguished by the lateral fissure, which is very frequently continued into a cleft palate. When one-sided, the imperfect union between the nasal and maxillary processes very often affects that between the corresponding palatal plate, the fellow of the opposite side and the vomer, and results in the cleft palate. With lip jaw clefts of the two sides, the defect of the palate may appear as a conspicuous median hiatus, in consequence of very imperfect formation of the plates, or the attempt at closure may result in leaving a slit on either side of the septum. The latter may be intact and attached to the intermaxillæ, which then sometimes present a snout-like protrusion.

Not rarely only part of the lines of juncture remain permanently ununited, as seen in cases in which slight indentations or linear scars on the lips, partially cleft palate, or split would alone persist as evidences of the imperfect closure. The observations of Friccius, covering 550 cases of harelip, showed the defect to be almost twice as frequent in males (62.5 per cent.) as in females (37.5 per cent.). It occurred on the left side in 52 per cent.; on the right in 21 per cent.; on both in 27 per cent. It was uncomplicated in 35.2 per cent., and complicated by alveolar or palatine cleft in 64.8 per cent. Hereditary influence was indicated in 11.5 per cent.

Occasionally the defective union involves the entire path of junction between the maxillary process and the internal and external nasal processes, the result being a cleft extending from the mouth, through the lip and superior maxillary bone, alongside of the nose, to the inner canthus of the eye. Such defect is known as primary *oblique facial cleft* (*cheilo-gnatho-prosoposchisis*), and is to be distinguished from similar, but less regular, secondary deformities sometimes arising from mechanical influences exerted by abnormal relations of the amnion. These latter defects may vary greatly in position, form, and extent, since they are accidental and do not represent suspension of normal lines of development, as do the primary clefts.

Nasal clefts, median or lateral, occur as rare malformations. The median involve the tip of the nose and depend upon the persistence of the original tubular form of nares separated by a deep groove. The lateral clefts occur in consequence of insufficient fusion of the external nasal with the fronto-labial processes. Lehmann-Nitsche [91] and Lexer [92] report interesting cases.

The mouth may also be the seat of malformations caused by defective union of the embryonal processes constituting its primary boundaries. Where these fail properly to fuse to form the usual lateral limits, the oral opening may remain as a widely open cleft (*macrostomus*), extending laterally almost or quite as far as the ear, on one or both sides. When less marked the defect is sometimes known as *cheek-cleft*. Abnormal fusion, on the contrary, may partially obliterate the oral opening (*microstomus*), this condition being sometimes associated with labio-maxillary clefts. Complete fusion with resulting closure (*astomus* or *atresia oris*) may also occur.

Malformations due to faulty development and union of the mandibular processes of the first visceral arch also occur, but are much less frequent than the foregoing facial clefts, owing to the greater number of processes concerned in the formation of the upper lip, nose, and upper segment of face, and hence the greater opportunity for incomplete fusion.

Defects of the *lower lip*, in the form of median cleft or fistulæ, are rare, since fusion of the mandibular processes takes place unless development be profoundly disturbed.

Micrognathus implies defective formation and growth of the embryonal bars, resulting in a rudimentary and under-sized condition of the lower jaw. Pronounced arrest of these processes may be shown in *agnathus*, in which the mandible may be seemingly totally wanting. According to Winckel and to Kuse,[93] however, rudiments of the inferior maxillary bone are always to be found by critical examination. In consequence of the disappearance of the mandible the external ears are shifted downward and inward until their approximation may become blending (*synotus*). Usually defective development of the ears and, not infrequently, also of the maxillary processes are associated with the malformations of the jaw. The mouth may be imperfectly represented and the lower part of the face appear as if cut off and occupied by a widely open pharyngeal recess.

Partial or complete duplication of the lower jaw (*dignathus*) is an expression of more or less extensive redundant differentiation of the mandibular processes. The doubling may involve only one side, or be limited to the alveolar processes, the accessory segment bearing supernumerary teeth. When partial the additional part projects from the mandible, or, when complete duplication occurs, may be fixed above or below the normal bone.

Cleft *tongue* may also exist as a rare malformation.

The external visceral furrows are the seat of abnormalities due to aberrations in the closure of these depressions between the adjacent arches. Variations in the development of the first furrow and its bordering arches give rise to malformations of the external ear.

Since the auricle is formed by the fusion and differentiation of six tubercles surrounding the outer end of the first furrow, defective development or imperfect union of these parts frequently produces malformations involving the pinna, including the auricular appendages which originate from displaced tubercles. Malformations of the auricle may be associated with closure or absence of the external auditory meatus due to partial or complete abnormal fusion of the first and second arches, with the consequent occlusion or disappearance of the external auditory canal. As already incidentally noted, malformations of the ears are sometimes associated with defective development of the face.

Congenital cervical fistulæ are the results of imperfect closure of the visceral furrows, coupled often with secondary rupture of the ecto-entoblastic epithelial septa, which in mammals separate the external furrows from the internal pharyngeal pouches. The most usual situation of the fistulæ is immediately above the sterno-clavicular articulation; less commonly along the anterior border of the sterno-mastoid muscle. Although it is difficult to determine the exact genetic relations of the fistulæ to the original furrows on account of the changes and displacement which occur during the evolution of the neck, it may be assumed, according to Kostanecki and Mielecki,[94] that the majority of these fistulæ are derived from the second furrow, between the second and third arches. Originally the fistula is only a short pocket separated from the corresponding pharyngeal pouch by the delicate occluding membrane formed by the opposed ectoblast and entoblast lining the outer and inner diverticula. This independence being retained, the fistula is only a short and narrow passage, directed upward and inward, soon ending blindly and without communication with the pharynx. When, as is not infrequently seen, fluids escape from the fistula on swallowing, we must assume that secondary rupture of the delicate epithelial septum has taken place, thereby establishing communication between the pharynx and the exterior.

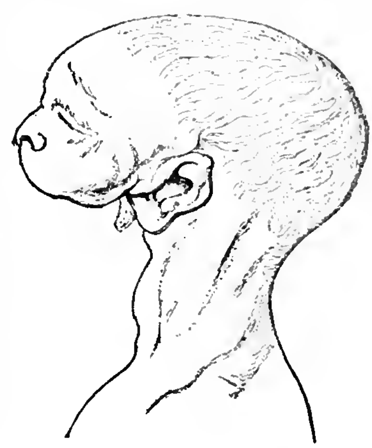

FIG. 4681.—Agnathus. (Guardan.)

Median cervical fistulæ constitute a group modified by the position of their external opening, which is central instead of lateral. As pointed out by Kostanecki, the outer opening of the fistulous passage corresponds to the remains of the precervical sinus of His; the latter is a median depression, resulting from the drawing inward of the blended lower visceral arches, which later becomes closed in by the union of the second arches with the thoracic wall. When complete, the fistulæ in question usually pass upward and inward, but end on the lateral wall of the pharynx in the same positions as do the lateral fistulæ. The median location of their outer end, therefore, must be regarded as secondary and supplementary in consequence of the primary visceral furrow being carried away from the surface and into the sinus, the remains of the latter persisting as the outlet of the original cleft. At times the remains of the precervical sinus alone appears as a median fistula, in which case a short passage is traceable downward instead of up.

Branchial Cysts.—The exceptional opportunities offered by the series of visceral arches and clefts for partial closure and the persistence of an isolated portion of the various furrows and pouches results in frequent production of various forms of cysts and tumors. The most common of these are simple cysts, which differ in character with their origin. If from the external furrows, they are lined with modified integument and are dermoid in type; if from the pharyngeal pouches, their lining approaches the columnar type and their contents are serous. As emphasized when considering true dermoids, the distinction between the productions of transplanted integumentary constituents and true fœtal inclusions, although often difficult, depends upon the presence of derivatives of all three germ layers. Since consideration of the various forms of branchial cysts and tumors does not fall within the province of this article, the reader is referred to the article on *Branchial Cysts* in Vol. II.

Defective or aberrant development of the pharyngeal pouches and the bordering arches may give rise to malformations of their derivatives.

The *tongue* may suffer from impaired development involving the region of the second arches, since its posterior third originates from the vicinity of their fused median ends, while its anterior two-thirds arises from the unpaired anlage, the tuberculum impar, which grows forward from the basal area. Faulty development of the anterior anlage results in deficiency or absence of the front part of the organ, although the base may be present. Glossal defects are often associated with micrognathus. Various degrees of attachment of the tongue to the floor of the mouth depend upon imperfect differentiation of its anterior anlage. Cleavage and partial doubling of the tongue is observed as a rarer malformation.

Persistence of the median anlage of the thyroid body as the thyro-glossal duct, the upper end of which is normally indicated by the foramen cæcum on the tongue, may give rise to a fistulous canal which descends to terminate in the vicinity of the hyoid bone, or in some cases to open as a median fistula in the neck. Isolated portions of the retained duct may become the seats of cysts.

Pharyngeal diverticula are occasionally observed, being due to local persistence of the inner visceral furrows.

Variations in the development of the *thyroid body* are also connected with the visceral arches, since the lateral anlages of this organ are derived as epithelial outgrowths from the fourth pharyngeal pouch and the median anlage as a similar outgrowth from the ventral wall of the pharynx in the vicinity of the second arches. Accessory thyroids occur in connection with both the lateral and the median lobe, those arising from the persisting remains of the embryonal condition of the latter appear at various levels, including a sublingual and a hyoid group. Disturbed development involving the thymus anlage of the third visceral cleft may lead to the formation of dermoid cysts which are subsequently carried into the anterior mediastinum.

When the closure of the precervical sinus remains very imperfect, the deficiency may lead to the rare malformation known as *cervical fissure*. Coupled with thinning and distention of the floor of the depression, the heart may project through the opening, thereby producing the rare suprathoracic type of *ectopia cordis*. The lungs and thymus have been observed to accompany the displaced heart.

Malformations of the Thorax and Abdomen Depending upon Imperfect Closure of the Ventral Body Wall.—The underlying process in the differentiation of the thoraco-abdominal cavity and the contained alimentary canal from the flat and widely extended germ layers is the ventral folding of the splanchnopleura and the somatopleura. By the approximation and union of the first folds is formed the digestive tube; by those of the second the ventral or anterior body wall, the intervening space being the primary pleuro-peritoneal cavity. In each case closure proceeds from all directions, cephalic, caudal, and lateral, the point of latest closure being the umbilicus, through which for a time the gut-tube communicates with the yolk-sac by means of the vitelline duct. Defective union of these ventral somatopleuric folds, the *membrana reuniens anterior*, results in a more or less extensive median cleft, which may be limited to a small portion of the thorax or abdomen, or involve the entire anterior body wall, reaching from the neck to the pelvis.

The most frequent seat of imperfect closure is at the umbilicus, this region in consequence of closure being here longest delayed, being inherently vulnerable. The simplest expression of such imperfection is *congenital umbilical hernia*, portions of the intestines and sometimes omentum protruding through a ring of unusual size. When the defective closure is more extensive and the abdominal contents are confined by a membranous wall composed of the peritoneum and the amnion covering the umbilical cord, the viscera may push before them the occluding membrane, which becomes converted into the hernial sac, lined by peritoneum and occupied by the displaced organs. This condition constitutes *omphalocele* or *funicular hernia*. The umbilical cord, being invaded by the hernial sac and contents, apparently springs from the sac near its apex or toward the side, the entire length of the cord frequently being greatly reduced. A large part of the abdominal organs may find its way into the hernial sac, which may contain, in addition to a variable length of intestine, a portion of the liver, the stomach, and the spleen.

When the defective union is still more extensive, the resulting fissure may involve the larger part or the whole of the ventral body wall. When limited to the abdomen, the condition is known as *gastroschisis completa;* when including also the chest wall, as *thoraco-gastroschisis*. In the former case the abdominal fissure is bounded by the ununited somatopleuric folds, which are directly continuous into the amnion. The latter, in conjunction with the peritoneum or alone, may constitute a considerable or even a huge sac, containing the greater part of the abdominal organs (*ectopia viscerum*). The ununited umbilical vessels may course in the wall of the sac without being collected into a distinct cord, the placenta in such cases being often fused with the sac. Spinal curvature, skoliosis, or lordosis is frequently associated with eventration. The thoracic involvement depends upon the extent of the sac; in exaggerated cases almost complete axial rotation with approximation of the upper and lower segments of the trunk may be present. The pelvis and the lower extremities may also share in the defective development, at times the limbs suffering complete backward luxation and extreme atrophy.

At times the defective closure of the abdominal wall is associated with fissure of the intestinal tube, usually in the vicinity of the beginning of the large intestine (cæcum or adjacent colon). The cleft gut is attached to the belly wall behind the opening through which the wall of the intestine may protrude (*ecstrophia intestini*.)

Fissure of the chest wall (*thoracoschisis*) may be coextensive with the anterior wall of the thorax, or it may be limited to the partial cleavage of the sternum alone. Since the latter is primarily formed by the blending of two curved vertical cartilaginous bars, arrest of union results in complete or partial fissure of the sternum. In the former case the isolated halves bear the costal cartilages and ribs; in the latter, the defective union may be limited and indicated by an opening in the gladiolus, or, more frequently, by fissure of the ensiform process. Rarely the defective development affects only one of the primary bars, this condition resulting in total absence of one-half of the sternum and the associated costal cartilages. When the defective union is extensive, owing to early arrest of development, the pericardium is uncovered or even wanting, and the heart displaced (*ectopia cordis*). According to the position of the protrusion, suprathoracic, thoracic, and subthoracic varieties of the ectopia are recognized, the second form, in which the heart escapes through the cleft sternum, being the most usual. The displacement of the heart into the abdominal cavity seen in the subthoracic ectopia is sometimes due to a defective diaphragm. When entirely exposed, as sometimes happens, life is prolonged only for a few hours after birth. Usually, however, the organ is more protected, and if the defect be small and the protrusion slight the malformation may be masked by the integumentary covering. Malformations of the heart itself, or of the great vessels, are not uncommon in marked ectopia. Concerning the cause of the arrested development involving the general thoracic wall, little is known, although it is certain that amniotic and other abnormal adhesions play an important part in bringing about displacement of the heart and in preventing union.

Subumbilical clefts result from faulty union of the anterior body wall invading the region below the navel, which may be the seat of fissures of varying extent, not only of the immediate abdominal parietes, but also of the associated organs, as the bladder and the external genitals. When the bladder is only slightly involved, the defect may be limited to a small *vesical fissure*, or, when the arrest of development is more extensive, the anterior wall of the organ may be entirely wanting and the exposed mucous membrane covering the postero-inferior wall of the bladder, with the openings of the ureters, be seen lying within the opening, constituting the condition known as *vesical ecstrophy* or *ectopia vesicæ*. At times displacement and complete turning inside out (*inversio vesicæ*) may accompany the cleavage as a secondary consequence of traction induced by unusual relations of the allantois and amnion. The pelvis, urethra, and penis are also seats of clefts associated with faulty union of the lower body wall.

Of the various *causes* to which extensive cleavage of the abdominal wall has been attributed, the most potent primary factor, as emphasized by Marchand, is to be sought in the early abnormal attachment between the ventrally placed vitelline sac and the chorion. This union interferes with the normal differentiation of the somatopleuric folds, which form the ventral body wall, from the amnion, the latter in a measure replacing the usual anterior parietes. In conjunction with these abnormalities a possible unusual dorsal union between the chorion and the amnion may hinder the expansion of the latter, with the result of inducing an early over-extension (lordosis) of the embryo, which further favors non-approximation of the component halves of the ventral body-wall and eventration. Early amniotic adhesions undoubtedly play an important rôle in subjecting the anterior parietes to abnormal tension and pull, in consequence of which arrest of development, delayed union, and displacement of organs may follow.

Malformations of the Diaphragm.—Since the partition subdividing the primitive body cavity into the pleuro-pericardial and peritoneal compartments is completed by fusion of segments which for a time are separate, arrested development or delayed union results in abnormal clefts. The formation of an antero-lateral fold —the *septum transversum*—early effects an incomplete isolation of the pleuro-pericardial cavities from the peritoneal space, and foreshadows the appearance of the primitive diaphragm. The latter is differentiated from the cephalic part of the septum, the caudal portion being intimately concerned with the development of the liver. The completion of the diaphragm is delayed for some time, an opening on either side of the primitive gut tube maintaining communication between the peritoneal and the pleural cavity. Finally, when the developing lungs have reached the young liver, the partition is completed by the forward growth of dorso-lateral folds, which fuse with the previously existing anterior segment. From the foregoing sketch it is evident that varying degrees of developmental arrest and delayed union may produce corresponding grades of imperfection in the septum. These include total absence or rudimentary condition of the diaphragm due to failure or insufficiency of development of the component primary folds. More frequently the defects result from the imperfect union of the anterior and posterior segments, and are therefore less extensive. The communications, larger or smaller in size, between the peritoneal and pleural cavities preserve the primary continuity of the serous membrane lining the abdominal and pulmonary spaces, the peritoneum passing directly into the pleura. In general, these defects occupy the posterior half of the diaphragm and are often in the vicinity of the œsophagus, the congenital orifices being much more frequent on the left than on the right. Other defects lie in the anterior part and correspond to the area of weakness between the sternal and adjoining costal portions.

The most conspicuous result of these imperfections is the displacement of organs as *diaphragmatic herniæ*. These may include a portion of the right lobe of the liver on the right, and the stomach, left liver lobe, spleen, and a variable part of the intestine on the left (E. Schwalbe [95]). Usually the dislocated viscera lie entirely free within the pleural cavity; exceptionally they are

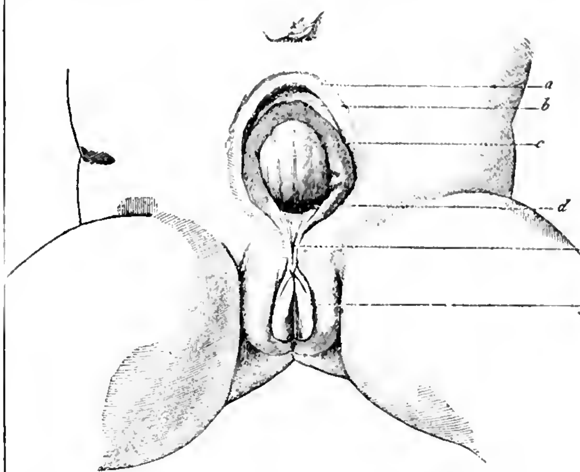

Fig. 4682.—Abdominal Fissure with Open Bladder. *a*, Skin; *b*, peritoneum; *c*, bladder; *d*, cavity of bladder; *e*, urethral groove; *f*, nymphæ. (Ziegler.)

enclosed within a hernial sac derived from the serous membrane. The influence of the intruding viscera upon the lungs and heart may be unfavorable, and these thoracic organs, particularly the lungs, in consequence often exhibit the effects of impeded development. The defective development of the diaphragm is frequently associated with other malformations, such as cleft sternum anteriorly, or imperfectly closed spinal canal dorsally. In certain cases of subthoracic *ectopia cordis* the heart escapes from the chest through the imperfections in the diaphragm, which are often associated with defective closure of the belly wall.

Malformations of the Digestive Tract.—*Mouth.* —Malformations of the boundaries of the oral cavity— the lips, cheeks, and palate—together with those of the jaws, usually depend upon arrested development and defective union of the embryonal processes which surround the primitive oral recess. These defects have been already considered under Facial Clefts (page 700).

The *tongue* likewise has been already considered in connection with imperfect development of the visceral arches (page 702), with the formation of which its origin is related.

The *pharynx* is the seat of fistulæ, cysts, and diverticula resulting from aberrant development of the primary pharyngeal pouches, in connection with which they have been noted (page 702). The slight dorsal recess which usually marks the transition of the pharynx into the œsophagus may be the starting-point of a considerable pouch extending between the spine and the gullet.

The *œsophagus* very rarely is entirely wanting or replaced by a fibrous cord; more usually the gullet is defective only in certain segments. Thus it may end blindly a short distance below the pharynx, or, on the other hand, its lumen may terminate above the stomach, the œsophagus being continued by a cord of fibrous tissue attached to the pharynx above. The atresia may be accompanied with more or less extensive dilatation, not infrequently associated with an abnormal opening into the lower part of the trachea (Hoffmann [96]). A divided condition of a portion of the œsophagus has also been observed.

The *stomach* is only rarely the seat of congenital mal-

Teratology.

formations. Its development may be imperfect, resulting in retention of the fœtal tubular form and under-size, the stomach at times being little larger than the succeeding gut. The organ may present constrictions, subdivisions, and dilatations. Sometimes the pyloric orifice may be partially or entirely closed, the stenosis being occasionally seen in infants. In company with other abdominal viscera, the stomach may suffer displacement in large congenital umbilical herniæ, as well as transposition in situs inversus. Total absence of the stomach may occur in acephalus.

The Intestines.—Partial persistence of the vitelline or omphalo-enteric duct in the form of *Meckel's diverticulum* is the most frequent congenital deformity of the intestinal tract. The duct for a time normally is pervious, but before birth it loses its lumen and is represented by an atrophic fibrous cord passing from the umbilicus to the ileum. When retained, the resulting diverticulum opens into the ileum, usually a little over a metre from the ileocolic valve. Its length varies from a mere shallow recess to the entire distance from the gut to the umbilicus; usually, however, it is some 10-13 cm. Its width at the intestine is commonly that of the gut, the blind extremity being somewhat less. The latter may exhibit a pouched condition, or a rounded end similar to the finger of a glove. The diverticulum usually springs from the convex side of the intestine, but may join the latter obliquely, or on the side of the attachment of the mesentery. In the latter case the diverticulum is provided with a process of mesentery. In exceptional cases the duct retains its lumen throughout, and on the disappearance of the stump of the cord after birth opens at the umbilicus, thus establishing a congenital umbilical *fistula*. Sometimes a small portion of the pervious duct remains attached to the umbilicus and becomes the basis of a tumor-like mass, which may yield a scanty secretion derived from the modified mucous membrane of the vitelline duct. The diverticulum may become constricted and its communication with the gut entirely lost, it remaining attached to the intestine as a cyst-like appendage. The latter may mark the seat of active growth resulting in the production of an intestinal cyst of huge size.

Total absence or extensive defects of the intestinal tube are always associated with grave general malformation, as in acardiac monsters.

Contraction and *closure* of the lumen of the intestinal tube may occur at different points, or a portion of the

FIG. 4683.—Atresia Ani with Rectum opening into Urethra. (Witt.)

gut may suffer obliteration. The upper part of the duodenum, in the vicinity of the entrance of the bile and pancreatic ducts, is a favorite position for interruption, the atresia of the gut being at times followed by extensive dilatation of the beginning of the duodenum in which the stomach may also be involved. The observation of Tandler,[97] that temporary constriction, or even occlusion, of the gut occurs near the entrance of the common bile duct during normal development of the duodenum, is suggestive in connection with atresia of this portion of the intestine. Ratz[98] reports an interesting case in which the small gut ended blindly, followed by the closed beginning of the large intestine. No evidences of inflammatory processes were present. The cæcum and appendix were wanting.

FIG. 4684.—Atresia of Rectum. *A*, Rectum connected with anal canal (*E*) by means of fibromuscular cord (*D*). (Guinard.)

Malformations of the *lowest segment* of the gut include an interesting group of defects sometimes dependent upon the faulty development of the parts concerned in forming the outlets of the intestinal and genito-urinary tracts. Reference to the early relation of these parts recalls that for a time a common space, the cloaca, receives the gut dorsally and the urogenital sinus ventrally. Separation of these tracts is effected by the extension of the urethro-rectal septum, which grows downward until it meets and fuses with the cloacal membrane closing the cloaca. This structure, the remains of the primary anal membrane, consists of the opposed entoblast and ectoblast and forms a temporary wall between the cloaca and the exterior of the body. Independent openings for the urogenital and intestinal canals are secured by the breaking down of the epithelial layers constituting the occluding membrane.

A conspicuous defect directly referable to arrested development is *persistence of the cloaca*, in which the rectum and urogenital sinus retain their primary relation, in consequence of the failure of the septum to appear, and open into a common space. The latter, closed by the still existing cloacal membrane, becomes distended by the accumulation of the excreta from the intestinal and urinary tracts. More usually the separation of the urogenital sinus and the gut is partially accomplished, the imperfection in the septum being represented by a permanent communication between the two canals; hence in the male the rectum opens into the urethra (usually the membranous but sometimes penile portion), or, rarely, into the bladder (*atresia ani vesicalis*). Occasionally the rectum empties into the vagina, very exceptionally into the uterus.

Imperforate anus (*atresia ani*) is relatively frequent and depends upon more or less extensive arrest of development of the gut, coupled with secondary attachments, which lead to the formation of a fibrous septum, closing the anus. The rectum may be well formed, or so defective (*atresia recti*) as to end blindly at some distance above the position of the anus, lying free and distended within the pelvic cavity. The atrophied gut may be attached by a fibrous cord without lumen. On the other hand, a well-developed anus may exist with closure of the rectum. In exceptional cases of imperforate ani, the rectal opening or fistula may lie farther forward and be found on the perineum, scrotum, or along the penis. The fistula may, on the other hand, be found over the sacral region, the unusual situation being probably associated with the primary dorsal position of the earliest trace of the anal depression, which under usual conditions acquires a more ventral location.

Variations in the form and situation of the *large intestine*, especially the colon and the cæcum, are very common, since the position and relations of this part of the intestine are greatly influenced by the torsion and secondary growth of the early gut tube. With the exception of stenosis, atresia, and possibly dilatation, the congenital defects are variations rather than malformations. Associated with these variations, modifications are also encountered in the arrangement of the peritoneum. The most striking of these is the retention of the fœtal simplicity of the mesentery (*mesenterum commune*), in which the duplicature enclosing the small intestine is directly continuous with the mesocolon and uncomplicated, the usual overhanging and anterior position of the large gut being absent, owing to the upward displacement of the latter having never occurred.

The *liver* is only seldom the seat of malformations, unless associated with general defects involving the intestinal canal, as in acephalic monsters, in which the organ is wanting. Very rarely absence of the liver may be unaccompanied by other malformations. The more usual, but still infrequent, defects include abnormalities in the size and number of the lobes; accessory or dislocated lobes may occur within the falciform ligament. Absence of the gall-bladder has been observed by Marchand in a child otherwise normal. Congenital stenosis of the bile passages, or enormous distention of the common duct due to obstruction near its termination in the duodenum, as well as unusual situations for the latter, are also occasionally encountered. Displacement and modified form are commonly seen in connection with umbilical and diaphragmatic herniæ or abdominal clefts.

The *pancreas* shares with the intestinal tube the effect of profound general malformation involving the alimentary canal. Supernumerary or accessory glands occasionally lie embedded within the intestinal, or at times gastric, wall. They may remain of small size and hidden, or they may become later in life the seat of cysts of large size. Unusual arrangement and abnormally situated openings of the pancreatic duct are dependent upon variations and connections in the development of the original anlages. The pancreas may suffer displacement in consequence of abnormal relations of the duodenum and stomach, or it may share the general inversion accompanying transposition of the viscera.

As a matter of convenience, the congenital defects of the spleen and of the suprarenal body may be here introduced, these organs having, of course, no connection with the digestive apparatus.

THE SPLEEN.—Very rarely the spleen is entirely wanting. Variations in the size of the normal organ include such a wide range that it is difficult to establish the limit of pathological defect. The most common malformation is the presence of one or more accessory spleens, which are usually found in the immediate vicinity of the chief organ, although they may lie at some distance or within the pancreas. H. Albrecht[99] has described a remarkable case of multiple spleens, in which a principal organ in the usual position was wanting and instead segments or supernumerary bodies to the number of almost four hundred were scattered throughout the abdomen. They occurred in groups which occupied the parietal peritoneum, the right half of the diaphragm, the upper surface and the falciform and coronary ligaments of the liver, the root of the mesentery, the splenic flexure of the colon, and the anterior surface of the rectum within the pouch of Douglas. Histological examination confirmed the macroscopic diagnosis of multiple accessory spleens. It is highly probable, however, that in many cases the supposed numerous minute accessory spleens are really hæmolymph glands of the splenic type (Warthin).

THE SUPRARENAL BODY.—The adrenals may rarely be wanting, or abnormally small, such defect being usually associated with deficient brain development (anencephalus). This relation, although recognized by the older writers, has been emphasized by Zander,[100] according to whom the development of the suprarenal suffers when the anterior half of the cerebrum is rudimentary; neither deficiency of the posterior part of the cerebral hemispheres and brain stem nor cerebral atrophy after the suprarenal has developed produces diminution of the latter.

The most frequent abnormality is the occurrence of accessory suprarenal bodies. The structures formerly described under this name included not only those connected with the adrenal or located in its more immediate neighborhood, as in the kidney or the liver, but also those found at a distance in the vicinity of the sexual glands, as in the broad ligaments or between the testicle and epididymis. The careful studies of Aichel[101] have shown that the last group represents constant organs of normal occurrence (*suprarenals*), which develop in relation with the atrophic tubules of the Wolffian body, and that the designation "accessory" is properly restricted to the supernumerary bodies which probably arise from constriction and isolation of a portion of the suprarenal anlage.

MALFORMATIONS OF THE RESPIRATORY TRACT.—The *nose*, in addition to the defects associated with facial clefts, may present congenital malformations involving defective development of the septum, ethmoid, nasal, and turbinated bones. Narrowing and closure of the posterior nares also occur.

The *larynx*, in common with other parts of the respiratory tract, may be entirely wanting, such conditions, however, being associated with grave malformations (acephalus) profoundly affecting the alimentary canal from which the pulmonary apparatus is the direct outgrowth. The congenital defects of the larynx consist usually of abnormalities affecting the cartilages, which may be increased in number, as a doubled epiglottis, or of the ventricle, which may be of unusual size with exaggeration of the lateral laryngeal pouch, the latter at times extending as far as the level of the hyoid bone and suggesting the laryngeal sacs seen in anthropoid apes. Abnormalities of the larynx as to size, excessive or deficient, as well as marked asymmetry, are occasionally observed. Complete closure of the larynx has also been recorded.

The *trachea* at times is absent, the respiratory tube undergoing bifurcation into the bronchi immediately below the larynx, or it may be only abnormally short. Contraction and occlusion also occur. Communication with the œsophagus has already been noted in relation to the defects of the gullet. The remains of such fistula may become a cyst connected with the posterior wall of the wind pipe. The cartilaginous rings are subject to variations in number and size in consequence of division or of fusion. Abnormal branching of the trachea into three bronchi is occasionally seen, the additional bronchus usually passes to the right upper lobe and is regarded by some (Chiari) as a supernumerary eparterial twig springing from the trachea instead of from the right bronchus. Herxheimer inclines to the view that the variation indicates the formation of an accessory lung. This author[102] has recorded an instance in which the first division of the trachea occurred 2.5 cm. below the cricoid cartilage, the right tube passing to a small nodule that presented all the histological characteristics of functionating pulmonary tissue. Rarely an additional eparterial or apical bronchus occurs on the left side in connection with a left lung possessing a third lobe (Chiari). Rudiments of supernumerary bronchi sometimes give rise to congenital diverticula.

The *lungs* are relatively infrequently the seat of primary congenital malformations, although the entire organ on one side may permanently remain uninflated and rudimentary. Such condition may be induced by the intrusion of abdominal viscera which have migrated into the thorax through a diaphragmatic hernia. More usually the defective development of the pulmonary tissue is limited to one part of the organ, the affected area consisting of branches of the bronchial tree surrounded by a relatively dense mass composed chiefly of highly vascular tissue without alveoli, the conversion of the primary epithelial bud-like divisions of the forming organ having never taken place. The bronchial tubes within the rudimentary area may appear normal, but they sometimes exhibit great dilatation and may be converted into congenital bronchial cysts, which may occupy a large part of the entire undeveloped area.

Variations in the number and size of the lobes are frequent, especially in the left lung, in which three lobes are not rarely seen. The division, according to Fürst, is commonly due to the presence of an unusual pleural fold, which effects cleavage of the developing lung. In certain instances the additional lobes may possess morphological interest, as pointed out by Schaffner, in connection with the right inferior accessory lobe, which he regards as the homologue of the constant cardiac lobe seen in other animals.

Rarely a rudimentary supernumerary or accessory lung, lying between the normal organ and the diaphragm, is formed in consequence either of an early division of the original anlage and isolation of the separated portion, or of the outgrowth of an additional independent anlage from the primitive gut tube. An interesting example probably involving such latter condition was recorded by Wechsberg.[10] The rudimentary lung was represented by an ovoid tumor, 5 cm. in its longest diameter, that projected into the left pleural sac, and was attached to the œsophagus by a thin stalk, about 2 mm. above the diaphragm. An aberrant course of the arching vena azygos major and the production of an unusual fold of parietal pleura have been held accountable for the presence of an isolated apical lobe in the right lung (Gruber).

MALFORMATIONS OF THE CIRCULATORY ORGANS.—Under this heading will be considered only the congenital defects of the heart and of the closely associated large blood-vessels, the discussion of the variations affecting the smaller vessels belonging less to the domain of teratology than to that of anatomy.

MALFORMATIONS OF THE HEART.—Since congenital defects of the heart largely result from arrested or perverted progress of development, a brief review of the salient features in the formation of this organ will aid in appreciating the significance of the malformations described.

After the fusion of the two, at first widely separated, anlages to form the single straight heart tube, the flexion and torsion of the latter results in the production of a flattened S like tube, of which the antero-inferior portion is the arterial and the postero-superior are the venous segments. These two divisions soon become partially separated by an external groove, which indicates the position of the auricular canal, the primitive auriculo-ventricular opening by which they communicate. The superior continuation of the arterial segment constitutes the truncus arteriosus. The subsequent conversion of the primary two-chambered heart into one, possessing right and left compartments, and of the truncus arteriosus into the aorta and the pulmonary artery is accomplished by the formation of a longitudinal partition consisting of three parts. 1. An interauricular septum, which, beginning in the fourth week on the upper and hind wall of the primitive auricle, grows downward toward the orifice into the ventricle and separates the original venous chamber into a right and a left half. This septum, however, is for a time incomplete, since until after birth it contains the foramen ovale, which permits the blood stream to pass directly from the right into the left auricle. 2. An interventricular septum, which, starting below, gradually effects the division of the common ventricular cavity into a right and a left ventricle. The primary auriculo-ventricular orifice likewise becomes differentiated into a right and a left division by the formation of the septum intermedium, produced by the downward growth of the interauricular partition, and its fusion with the thickened margins of the auricular canal. The separation of the two ventricles is completed last in the upper part of the interventricular septum, where for a time communication between the two sides persists. 3. An arterial septum, which starting some distance above, extends downward toward the heart to meet the interventricular partition and divide the truncus arteriosus into the pulmonary artery and the aorta, which then communicate with the right and left ventricles respectively. The primary disposition of these vessels is such that the aorta lies directly in front of the pulmonary artery; their later relations to each other and to the heart chambers are acquired secondarily in consequence of the rotation and torsion to which they are subjected during development.

Malformations of the septum constitute the most frequent congenital defects of the heart; of these the imperfections of the *interauricular* partition are most common. That such should be the case is to be expected, since the existence of the foramen ovale predisposes to defects of the septum. The *persistence of the foramen ovale* may be complete, with correspondingly large opening; more usually partial closure has taken place, leaving sometimes only a mere cleft between the anterior margin of the foramen and its valve. Fawcett and Blackford[104] conclude that faulty closure of the foramen ovale exists in 28.3 per cent., the opening (most common in female subjects) varying from 1 to 15 mm. A much rarer defect at times occurs at the lower part of the interauricular partition due to faulty union between the latter and the lips of the primitive aural canal. *Total deficiency* of the interauricular septum, a three-chambered heart resulting, occurs very rarely and then in conjunction with other grave defects.

The *interventricular septum* is the seat of defects much less frequently than is the wall separating the auricles. When present, these malformations usually occupy the upper and anterior part of the septum, known as the pars membranacea. This corresponds to the position in which closure is last effected by union of the upward growing crescentic inferior fold, the septum intermedium and the partition dividing the truncus arteriosus into aorta and pulmonary artery. Since the last-named partition is concerned in completing the interventricular wall, imperfections in the latter are not infrequently associated with malposition of the former. This condition may result in disproportionate division of the lower end of the truncus arteriosus, the aortic orifice being enlarged at the expense of that of the pulmonary artery. Complete absence of the interventricular septum may occur, or even failure of both the auricular and ventricular parts of the general longitudinal partition, the heart under such conditions containing but two chambers.

Malformations of the great vessels are connected with the imperfect or perverted development of the septum, which is formed within the truncus arteriosus by the union of two elevations from opposite sides of the vessel. Normally the equal subdivision of the latter vessel is insured by the median position of the partition. Deviations from this by the ridges forming nearer one wall than the other evidently must lead to disproportion in the size of the resulting vessels, the aorta and the pulmonary artery. Such defects are frequently associated with imperfections of the interventricular partition, since the septum within the truncus takes part in the division of the ventricular chamber by joining the upward growing fold. Sometimes, however, extensive deficiency of the aortico-pulmonary septum may exist with normal valves, as in the case described by Hektoen.[105]

Abnormalities in the *number of the leaflets* of the aortic and pulmonary semilunar valves include both increase and decrease. Such congenital variations are usually referable to atypical division of the four primary leaflets which guard the lower end of the truncus arteriosus. When separation of the latter into two new vessels occurs, each elongated lateral primary leaflet is subdivided, of the six resulting segments three going to form the aortic and the pulmonary valve each. Fusion and cleavage of the original segments are responsible for diminution and increase of the leaflets guarding these openings, which may be so few as two or so many as five. The variations produced by pathological processes affecting the valves are manifestly beyond the present consideration.

Stenosis of the pulmonary artery, commonly coupled with narrowing or closure of its cardiac orifice with defective semilunar valves and possibly contracted conus arteriosus, is not infrequent. Although this malformation may exist unaccompanied with a defective interventricular septum, it frequently occurs associated with the latter condition. Deflection of the septum of the truncus may result in abnormal origin of the great vessels, both being connected with the right ventricle, or transposition of their usual relations occurring, the aorta springing from the right ventricle and the pulmonary artery from the left.

Stenosis of the ascending aorta with excessive size of the pulmonary artery sometimes exists, but is far less common than the opposite condition. Such narrowing may likewise occur independently or in conjunction with septal and other defects. Local constriction, or even complete closure and obliteration, at times takes place, as at the "isthmus" between the left subclavian artery and the ductus arteriosus, in consequence of which the circulation is maintained by the enlarged collateral vessels.

Persistence of the ductus arteriosus may occur without other defect, or it may be a compensatory retention, as when the narrowing of the pulmonary orifice exists to a degree that renders necessary the persistence of the vessel as the means of maintaining an adequate pulmonic circulation, the lungs being supplied by the blood that passes into the pulmonary arteries from the aorta by way of the ductus arteriosus. Stenosis of the aortic valve when of high degree is usually associated with feeble development of the left side of the heart and persistence of both the ductus arteriosus and the foramen ovale. By these channels the blood forced into the pulmonary artery partly passes by the ductus into the aorta and general circulation, while the foramen ovale provides the means by which the blood returned from the lungs may escape into the right auricle to mingle with that eventually propelled from the right ventricle.

The *auriculo-ventricular valves* may also present variations involving the number of the segments and the size of the opening. Such defects depend upon abnormal position, fusion or cleavage of the pad-like thickenings, and elevations of the margins of the orifices from which the leaflets are formed. Congenital narrowing, closure or obliteration of the auriculo-ventricular apertures may occur in consequence of fusion of the early segments, or of deflection and union of the septum intermedium with one side of the opening. When closure of the latter is complete, the maintenance of the circulation is possible only when a defective septum exists.

Abnormalities in the number and arrangement of the papillary muscles, the presence of unusual bands, the excessive prominence of the columnæ carneæ, the honeycombed myocardium, etc., depend upon faulty development and consolidation of the muscular heart, which at first consists of a network of contractile trabeculæ.

Variations in the openings of the venous trunks emptying into the right auricle also occur and are dependent upon arrested or disturbed development of the sinus venosus. The latter vessel, the common chamber for the reception of the venous trunks returning the blood to the heart, communicates with the primitive auricle by a single large opening guarded by two valves, a right and left. With the growth and expansion of the heart, the sinus venosus loses its independence and is drawn into the auricle, of which it constitutes the posterior portion. In consequence of this change, the tributaries of the sinus now open by separate apertures directly into the right auricle as the two cavæ and the coronary sinus. Should arrested development prevent the absorption of the sinus, the venous trunks may communicate with the auricle by a common orifice. Stenosis and atresia of these apertures sometimes are observed. The thread-like trabeculæ, at times forming networks, which are occasionally attached to the Eustachian and Thebesian valves, represent, according to Chiari, the remains of the septum spurium and the right valve, which originally guarded the entrance of the sinus venosus.

Variations in the manner in which the *pulmonary veins* terminate in the left auricle are explained by the early relation of these vessels to the heart. The four pulmonary veins at first join to form a single trunk, which empties into the left side of the original auricular division of the young heart before the organ is separated into a right and left half. With the growth and expansion of the auricle, the short single vessel disappears in the heart wall and the separate pulmonary veins open into the auricle by independent openings. Where the extra-cardiac union is more extensive than usual, or the absorption of the primary single trunk is imperfect, the early relations persist, resulting in a simple, double, or triple venous opening.

The *large arterial trunks* arising from the arch of the aorta frequently present variations in their origin and course, which are referable to abnormal metamorphosis of the five pairs of aortic arches given off from the ventral continuation of the truncus arteriosus. The detailed consideration of these anomalies, which especially involve the innominate, common carotid, and subclavian arteries, belong to descriptive anatomy rather than to teratology. The rare occurrence of double aortæ is to be referred to the persistence of the two trunks of early embryonic life.

The *great venous trunks* entering the heart are subject to abnormalities which depend upon either defective development of vessels formed secondarily, or persistence of primary vessels that usually disappear, or at most are of small size. Results of the first cause are seen in the absence of the inferior vena cava above the renal veins, of the left innominate and of the left common iliac vein.

Examples of abnormal persistence are encountered in the presence of the left cardinal veins and of a left duct of Cuvier in the form of exaggerated hemiazygos veins and a left superior cava respectively. Very usually the retention and excessive size of primary veins which ordinarily atrophy are compensatory and due to the defective development or absence of important secondary trunks.

Malposition or transposition of the heart (dextro-cardia), in which the relations of the organ and its great blood-vessels are accurately preserved in reversed order, is usually associated with general situs inversus involving all the viscera within the body cavities. This condition has been already considered. Very rarely the transposition affects the heart and great vessels alone, the remaining thoracic and abdominal organs retaining their normal positions. Reference has been previously made to the partial transposition which may involve the aorta and pulmonary artery and the ventricles in consequence of faulty division and torsion of the truncus arteriosus. Durante[106] describes a striking example of this malposition. The displacement which the heart suffers in conjunction with extensive clefts of the ventral body wall may result in an extra-thoracic position of that organ (*ectopia cordis*). Doubling of the heart has been described as a very rare malformation. Its possible occurrence is ascribed to imperfect fusion and continued independence of the two primary heart tubes, which ordinarily blend to form a single organ.

MALFORMATIONS OF THE URO-GENITAL ORGANS.—*The Kidney*.—In rare cases and often coupled with other grave defects, both kidneys may be totally wanting, or so rudimentary as to be practically absent, being represented by only meagre suggestions of renal tissue. Dykerhoff[107] has called attention to the fact, and described an illustrative case, that living and otherwise well developed children are sometimes born with aplasia of high degree of both kidneys and obliteration of the ureters. Such defects evidently lead to death within a short time after birth. Since the epithelial elements of the organ are derived as expansions of the primitive ureter, which in turn is an outgrowth from the Wolffian duct, the rudimentary condition of the kidney is usually associated with imperfect development of its excretory duct. More frequently only one kidney, most often the left, is rudimentary, in which case congenital compensatory hypertrophy of the one present exists. Deficiency of both organs is manifestly incompatible with life.

The commoner malformations of the kidneys include various degrees of *fusion* and *displacement*. Union of the two organs at their lower ends produces the *horseshoe kidney* often observed. The connection varies in position, size, and intimacy, in some cases the union being little more than apposition; in others a fibrous band forms the junction, while at times actual fusion of the renal tissue takes place. Much less commonly the intervening bridge may occupy the upper or middle portion of the adjacent surface, or the entire opposed borders of the two organs may be united. Two separate pelves and ureters are usually present, the latter sometimes crossing the anterior surface.

When intimately united *displacement* of one of the kidneys often occurs so that both lie on the same side of the spine, the one over the other. Complete fusion of the kidneys sometimes results in a median, flattened renal mass which usually lies in the vicinity of the pelvic brim, sometimes below the promontory of the sacrum, within the pelvis. The common sinus contains a single or double pelvis, from which proceed one or more ureters. Rarely the fused kidneys occupy a lateral instead of a median position. Displacement of the kidneys is usually associated with abnormal arrangement of the renal arteries and veins, the former springing from the adjacent portion of the aorta or common iliac arteries, the veins ending in corresponding localities into the inferior cava or common iliac veins.

Lobulation of the kidney depends upon the persistence of a condition which, while normally seen during fœtal life, ordinarily disappears in the human fœtus before birth. The superficial areas correspond to the bases of the pyramidal lobules of which the immature human kidney is composed.

The Ureter.—Doubling of the excretory canal of the kidney, on one or both sides, is occasionally observed. It may involve the renal pelvis alone, or extend to the ureter, either to the upper part or throughout its entire length. In the latter case the ureters open by independent orifices into the bladder. Gallusser[108] reported the presence of four ureters, two for each kidney, three of which opened into the bladder, while one ended blindly. The ureters may be abnormally short owing to pelvic displacement of the kidney. They are also the seat of irregular constrictions leading to congenital cyst formations.

Abnormal situations at which the ureters may terminate include the seminal vesicles, prostatic urethra and rectum in the male, and the urethra, the vagina, and uterus in the female. The explanation of these aberrant endings is found in the early embryological relations of the Wolffian duct, the cloaca, and the Müllerian duct. Since both ureter and seminal vesicle are the outgrowths from the Wolffian duct, unusual proximity of their embryonal relations may result in later union. Failure in the normal migration of the lower end of the ureter, whereby its point of termination in the urogenital sinus (later the prostatic urethra) is changed to the bladder, results in persistence of the primary close relations to the vas deferens, the representative of the Wolffian duct. Early displacements may bring the primitive ureter into abnormal relations with the hind gut, resulting in the subsequent ending of the ureter in the rectum. The early close association between the primitive renal, Wolffian, and Müllerian ducts accounts for the exceptional ending of the ureter in the vagina or uterus. Occlusions of the urinary duct in consequence of congenital narrowing and closure of the renal pelvis or ureters may take place, resulting in obstruction to the escape of the urine and distention of the tube.

The Bladder.—The urinary bladder is the seat of profound malformations resulting from arrested and imperfect development affecting the cloaca and the allantoic duct. The latter, an outgrowth from the gut tube, extends from the antero-ventral end of the cloaca for a limited distance within the belly-stalk, its intra-embryonic segment contributing the urachus and the upper part of the bladder.

While usually losing its lumen and persisting as a fibrous cord, the median vesical ligament, the urachus not infrequently remains partially pervious in its lower portion, forming either a narrow tube, lined with epithelium, or a small cyst. Exceptionally the pervious portion may communicate with the bladder and become distended. Occasionally, particularly when obstruction of the urethra takes place at an early period, the urachus may retain its lumen throughout and exist after birth as a tube which connects the bladder with the exterior of the body at the umbilicus, constituting a *uracho-vesical fistula*, through which urine may escape. In rare instances persistence of the urachus may lead to the formation of a fissure at the umbilicus of sufficient size to permit the escape of the bladder (*ectopia vesicæ*).

Vesical fissure, the most important malformation of the bladder, is associated with cleft ventral body wall, of greater or less extent, through which the posterior vesical wall appears as a red mucous surface, usually somewhat modified. The orifices of the ureters are often visible. The edges of the cleft bladder are attached to those of the external fissure, the integument and the lining of the bladder being continuous. This condition of *vesical exstrophy* may give place to complete prolapse or *inversio vesicæ*. When the cleavage is extensive it may reach from the umbilicus as far as the anus, involving the pelvis, abdominal walls, and external genital organs (*fissura abdomino-vesico-genitalis*). Vesical fissures, much more common in the male, are frequently associated with rudimentary development of the penis and dorsal cleavage of the urethra (*epispadias*). When the vesico-abdominal cleft is extensive, the posterior bladder wall is sometimes subdivided more or less completely, projecting prolapsed portions of the gut tube intervening. Pubic fissure when present may be accompanied by prolapse of the bladder and gut, causing wide separation of the halves of the cleft external genital organs, including penis or clitoris, scrotum or labia majora, as well as displacement and prevented fusion of the Müllerian ducts, resulting in double vagina and uteri.

Complete absence of the bladder, uncomplicated by other malformations, in consequence of failure of differentiation, occurs very rarely; in such cases the ureters open into the urethra, since the latter then represents the part of the cloaca which normally contributes the lower part of the bladder. Abnormal smallness of the latter is not infrequent. Subdivision of the bladder into two compartments, a larger upper and a smaller lower, sometimes occurs, the constriction in a general way indicating the extent of the allantoic and cloacal portions of the organ. Longitudinal division of the bladder, varying in completeness, has been rarely noted and probably depends upon doubling of the allantoic duct.

The attempt to explain satisfactorily the production of vesical fissure has occasioned much discussion, authorities even at present being by no means in accord. The older theories attributing the cleavage of the vesical and body wall to mechanical influences, such as overdistention of the bladder or rectum by excretions, or unusual traction of the umbilical cord, may be dismissed as entirely inadequate. Zander[109] regards persistence of the dorsal concavity, which normally for a time distinguishes the contour of the early human embryo, as an important factor in the production of these malformations. Failure to assume the normal ventral curve has been attributed to unusual constriction or attachment of the amnion. Although still uncertain as to details, it may be assumed that these clefts are the result of a very early arrest of development involving the primary structures concerned in forming and in differentiating the cloaca, urogenital sinus, and rectum. The studies of Retterer [110] and of Keibel [111] have thrown much light upon the close relations of the cloaca to the normal development of the bladder. The last-mentioned investigator regards the fissures in question as the result of primary imperfection in the development of the ventral walls and bladder referable to faulty closure of the primitive streak. However that may prove to be, it is certain that the defects under consideration are due to a very early developmental arrest.

The Urethra.—The urinary canal, in both sexes, may be wanting, partly occluded or narrowed, due to imperfect development and more or less marked closure of the urogenital sinus. The urethra in the male consists of two embryologically distinct portions. The one, corresponding to the prostatic and membranous segments, is derived directly from the urogenital sinus; the other is formed by the prolongation and fusion of the primary genital folds along the under surface of the developing corpora cavernosa and includes the penile portion of the urethra. Faulty development and coalescence of these folds result in the production of a cleft and imperfect urethra, the abnormal termination of which may be at any point along the under surface of the more or less rudimentary penis. This condition, known as *hypospadias* and relatively common, depends upon faulty development and imperfect fusion of parts which normally exist in duplicate and unite. In the lowest grades of the defect the cleft is limited to the glans; in extreme cases the fissure may extend not only to the root of the penis, but also involve the scrotum, the component halves of which remain separate and unfused, the urethra being open as far as the prostatic segment.

Epispadias, in which the urethral cleft is associated with dorsal fissure of the penis or clitoris, is not only comparatively rare, but much less evident in its mode of production. Since the genital eminence, giving rise to the chief part of the penis or clitoris, exists as an unpaired anlage, the cleavage implies a profound defect and impression at an early period. This malformation is usually associated with vesico-abdominal fissure, very rarely existing alone, hence its genesis is usually regarded as closely identified with the influences producing the more general clefts. In many cases the dorsal groove exposing the urethra, when coincident with vesico-abdominal fissure, extends as far as the bladder, into which it opens in the vicinity of the trigonum. Doubling of the urethra sometimes occurs in consequence of faulty union of the two component halves. In a case described by Löw [112] the two canals opened by independent orifices in the navicular fossa, the smaller and upper tube extending as far back as the prostatic segment.

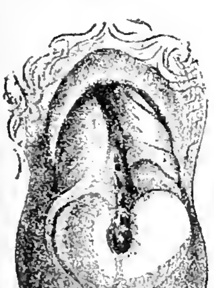

FIG. 4685.—Epispadias. (Hahn.)

MALFORMATIONS OF THE SEXUAL GLANDS AND THEIR DUCTS.—*The Testicle.*—Congenital absence of one or both male sexual glands has been rarely observed. More frequently the defect is only partial, affecting either the testicle itself or its excretory duct. In addition to the imperfections manifested in the epididymis and vas deferens in sympathy with defects of the testicle, these structures may be the seat of independent faulty development.

The most common defect of the testicle is its malposition, occasioned usually by incomplete descent into the scrotum, a migration normally accomplished shortly before birth. The undescended testicle may be retained within the abdomen (*cryptorchism*), either in its primary lumbar position or lodged at the inner end of the inguinal canal. Displacements within the abdominal wall, in front of the external abdominal ring, or within the perineum constitute respectively the inguinal, pubic, or perineal forms of ectopia. One or both testicles may be affected, and, as a great rarity, both organs have been seen to occupy the same peritoneal sac. Frequently the retained organ suffers atrophy, or at least fails to undergo perfect development at puberty.

Malposition or even complete inversion of the descended testicle within the scrotum sometimes takes place in consequence of abnormal attachment and traction of the ligamentum scrotale.

Doubling of the testicle has been observed (Lossen [113]) as a very rare malformation which depends upon subdivision of the primary anlage of the sexual gland. The presence of a single common excretory duct in such cases is explained by the independent origin of the latter from the Wolffian body.

The Ovary.—The absence of both ovaries rarely observed, as well as the more common deficiency of one, is usually associated with other malformations of the generative organs. Sometimes, however, such defects exist along with well-formed oviducts and uterus. In most cases it is probable that absence of the ovary is due to abnormal relations and attachments of adjacent structures, in consequence of which the development of the ovarian anlage is arrested and atrophy follows.

Not infrequently the ovary remains rudimentary, its function as an egg-producing organ being never, or at best only imperfectly, assumed. The ovary may be doubled (Civatte [114]), the supernumerary organ originating from constriction and isolation of a part of the primary anlage, or of the young organ at very early stage.

Malposition of the ovary may occur in consequence of the gland becoming engaged in the inguinal canal and descending into the labium majus. At other times it escapes through the femoral or the obturator canal, or suffers displacement within the pelvis due to abnormalities of the uterus and its attachments.

The Oviducts.—Entire absence of the Fallopian tubes is usually associated with grave malformations of other portions of the generative tract; on the other hand, normal oviducts may exist when the uterus and vagina are defective. Local arrest of the development of the tubes is exhibited in the stenosis and atresia, which may affect either the uterine or abdominal orifices or the intervening portions of the duct, which are at times reduced to a solid cord. Supernumerary abdominal orifices are also encountered (Nagel [115]).

The *uterus* and the *vagina* are subject to malformations arising largely in consequence of imperfect development and faulty fusion of the two Müllerian ducts of the major part, of which these organs are the direct representatives. Normally during the third month of fœtal life the portions of the Müllerian tubes included within the genital cord unite to form a single canal, the upper part of which becomes the uterus, the lower the vagina. The fundus of the uterus for a time is divided into two horns, which are directly continuous with the oviducts, the ununited portions of the Müllerian ducts. Later the uterine horns become incorporated with the fundus.

Imperfect fusion of the Müllerian ducts throughout areas in which union normally takes place results in more or less complete doubling of the uterus and vagina. The duplicity may be effected by a septum within an externally apparently single organ, thereby producing a *bilocular* uterus or vagina. The partition is often limited to one part of the uterus, as the fundus or the cervical segment, or it may imperfectly divide the vagina.

The results of imperfect external fusion of the Müllerian ducts are seen most markedly in the uterus, which then retains the early *bicornate* condition in varying degrees. When the duplicity is restricted to a slight indentation of the fundus (*uterus arcuatus*) the lack of fusion is merely suggested. From this condition all gradations are seen to the complete separation of the tubes (*uterus bipartitus*), at times involving the entire utero-vaginal tract (*uterus didelphys*).

The Müllerian duct of one side may undergo partial obliteration, occasioning the closure and disappearance of the corresponding portion of the doubled uterus, in which one horn may be represented by a solid cord (*uterus unicornis*). Unilateral arrest of development may also affect the Müllerian ducts as shown, when of slight degree, by the asymmetry and obliquity of the uterine fundus. Very rarely the fused ducts may remain so rudimentary that later they are represented by only a solid muscular nodule or cord.

Not infrequently the uterus retains the *infantile form* in consequence of failure of the body segment fully to develop, the cervical portion being unusually prominent as in early life.

The *vagina*, having similar relations to the Müllerian ducts, is subject to the same congenital duplicity as the uterus, although the septum is frequently partial and incomplete. One of the two canals may be partly obliterated by unilateral arrested development of the embryonal tubes. The vagina is very rarely entirely absent. The more usual malformations, however, include narrowing or closure, especially of the upper portion. Congenital vaginal stenosis is often associated with a similar condition, or obliteration, of the uterine cervical canal. Persistence of the infantile type of uterus is usually accompanied by stenosis of the vagina, although the vaginal defects may exist independently of abnormalities of the upper segments of the genital tract. The vagina may be partially represented by a solid cord. The *hymen* is seldom absent; the imperforate, annular, and cribriform types are some of the variations which this duplicature presents.

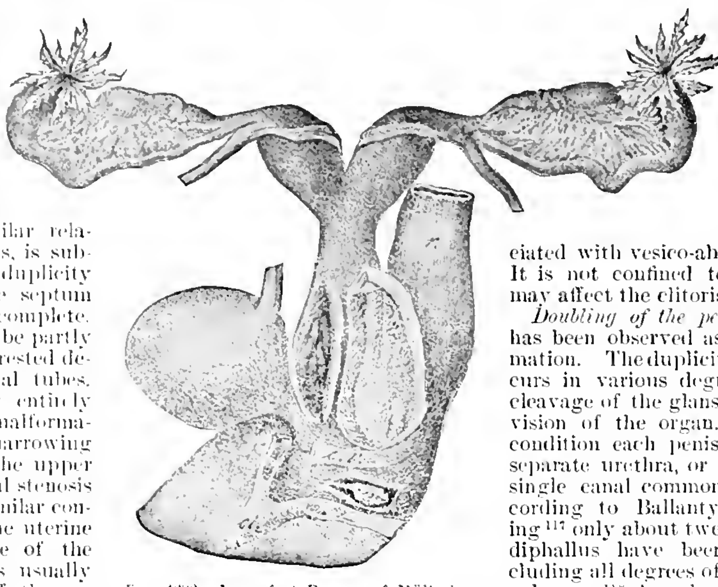

FIG. 4686.—Imperfect Fusion of Müllerian Ducts Resulting in Double Uterus and Vagina. (Schröder.)

MALFORMATIONS OF THE EXTERNAL SEXUAL ORGANS.—The external generative organs of both sexes are derived from three sets of structures—the *genital eminence*, the *genital ridges*, and the *genital folds*—which until the close of the third fœtal month are sexually undifferentiated. Elongation and fusion of these embryonal parts characterize the development of the male organs, while those of the female retain the original separated condition of their constituents.

The Male Organs.—The penis is evolved by the growth and extension of the unpaired genital eminence (from which are derived the corpora cavernosa), in conjunction with the elongation and fusion of the urethral ridges contributed by the walls of the urogenital sinus and the genital folds (from which are formed the corpus spongiosum and the urethra).

The penis may be entirely wanting, although this rare defect is usually associated with other malformations of the external genital organs. More frequently its development is rudimentary in consequence of which the organ remains small and clitoris-like. Arrested or faulty union of the folds, derived from the walls of the urogenital sinus, results in the production of a cleft along the under side of the penis (*hypospadias*) by which the urethra is opened, its termination lying at any point between the glands and the scrotum. When the arrest of development occurs at an early period, the cleft may be extensive and the urogenital sinus may remain entirely open. In such extreme cases the genital ridges, which normally unite to form the scrotum, may persist as separate folds embracing the hypospadial fissure. *Occlusion* and partial *obliteration of the urethra*, on the other hand, may occur in consequence of secondary excessive fusion of the uniting folds, or, when located at the glans, due to persistence if the epithelial urethral septum. Excessive size of the urethral crest surrounding the sinus pocularis has also been found responsible for closure of the urethra (Fuchs[116]). Enormous distention of the bladder and dilatation of the ureters are natural consequences of the obstruction of the urinary passageway. The urethra frequently communicates with the rectum in cases of atresia ani and, in the female, with the vagina when imperfect differentiation in the urogenital sinus exists.

The much rarer dorsal cleft (*epispadias*) is, as already pointed out above, usually associated with vesico-abdominal fissure. It is not confined to the male, but may affect the clitoris as well.

Doubling of the penis (or *clitoris*) has been observed as a rare malformation. The duplicity (*diphallus*) occurs in various degrees, from mere cleavage of the glans to complete division of the organ. In the latter condition each penis may enclose a separate urethra, or there may be a single canal common to both. According to Ballantyne and Skirving[117] only about twenty instances of diphallus have been recorded, including all degrees of duplicity.

Lange[118] has described an additional interesting case in which the two penises lay side by side, each connected with a scrotal sac containing a single testicle. There were two urethræ and two entirely distinct bladders, each with one ureter. The rectum was without anal opening and communicated with both urethræ. This condition, since the primary genital eminence is unpaired, probably depends upon profound early defects involving the cloaca and the urogenital sinus similar to those responsible for the production of epispadias and exstrophy of the bladder.

In rare instances the termination of the Wolffian ducts, later the seminal ducts, is continued during the development of the penis as an independent canal, the urethra being coincidently formed as a second one. In such cases the penis may contain two canals, the one for the products of the sexual glands, the other for the urine. Absence of the prepuce rarely occurs; oftener an abnormal shortening. On the other hand, not infrequently an unusual congenital redundancy exists.

The Female Organs.—In rare instances the external genital organs may be wanting, or so rudimentary that little differentiation into distinct parts takes place. On the other hand, congenital hypertrophy of the clitoris or labia is occasionally seen. Neugebauer[119] has reported the case of a young woman of twenty-two years who possessed a second clitoris, about one inch long, attached to the perineum. it presented the appearance of a diminutive penis, having perfect glans, corpora cavernosa, and partial prepuce, but was imperforate. There where no signs of testicles or other abnormal conditions. Chiarleoni[120] described a remarkable case, that of a child of about three years, in which there were two sets of external genitals, each possessing labia minora and vestibule; on the left side a clitoris was present, below which opened a minute orifice for urine and fæces. A similar aperture opened into the right vestibule. An anus was wanting. The most conspicuous malformations are those arising from an attempt to follow the male type of development. In consequence of such deviation union of the genital folds and ridges takes place, resulting in closure of the vestibule and vagina. Since these malformations play an important part in the production of certain hermaphroditic forms, their consideration is appropriately included under the discussion of that subject.

Hermaphroditic Malformations.

Since the generative organs of the two sexes are differentiated from embryonal structures which are for a time common and neutral, it is not surprising that at times their development is irregular and results in the production of aberrant forms, in which certain characteristics of one sex are combined with those of the other. This applies especially to the generative ducts and the external organs, the sexual glands being very rarely of more than one type in the same individual.

In comparing the various types of sex duplicity it is necessary to bear in mind the salient features of the development of the sexual organs. The latter are produced by three independent but coincident processes: (*a*) the formation of the sexual glands; (*b*) the formation of the excretory ducts; (*c*) the formation of the external genitals.

The sexual gland develops from an anlage in the immediate vicinity of the Wolffian body; for a time indifferent, it later differentiates into testicle or ovary.

The Wolffian body consists essentially of the transverse tubules and their common canal, the Wolffian duct. An additional tube, the Müllerian duct, lies parallel to the former. The four tubes—the two Wolffian and two Müllerian ducts—are associated as the genital cord and open on the posterior wall of the urogenital sinus.

In the development of the male excretory passages, the Wolffian tubules and duct take the most important part, forming the vasa efferentia and coni vasculosa, and the tube of the epididymis and the vas deferens respectively. The Müllerian duct in the male is largely atrophic, remains of its upper extremity persisting as the unstalked hydatid connected with the globus major of the epididymis, while the fused lower ends of the two ducts are represented by the sinus pocularis, or uterus masculinus, on the posterior wall of the prostatic urethra. The sinus pocularis is, therefore, the homologue of the vagina and possibly the uterus. When the intermediate part of the Müllerian duct persists, it constitutes the duct of Rathke.

In the female type the active factors are the Müllerian ducts, the upper segments of which remain separate to become the oviducts, while the remaining parts unite and fuse into a common tube, which becomes the uterus and the vagina. The upper part of the Wolffian duct and some of the associated tubules persist as the epioöphoron, or the organ of Rosenmüller, the homologue of the globus major of the epididymis. The remaining parts of the Wolffian ducts ordinarily disappear, or at best remain to a limited extent as the tubules of Skene, which lie on either side of the vagina. Exceptionally the Wolffian duct persists and is then known as Gärtner's duct.

The external generative organs arise from the genital eminence, genital folds and genital ridges, in conjunction with the urogenital sinus. In the male the genital eminence enlarges to form the corpora cavernosa, the spongy body being formed by the extension of the walls of the urogenital sinus and the genital folds. The scrotum represents the fused and enlarged genital ridges, the raphe indicating the line of union. In the female the original separated relation of the genital ridges and folds persists, the former becoming the labia majora, the latter the nymphæ, while the genital eminence forms the clitoris. The urogenital sinus contributes the urethra and the vestibule.

The duplicity of sex in the same individual implied in the condition termed "hermaphroditism" is almost always only apparent and not real, since response to the crucial test, to be applied to every case by microscopical examination, as to the presence of both forms of sexual glands is rarely affirmative. Hermaphroditism is therefore divided into *true* and *false*.

True Hermaphroditism.—True sexual duplicity (*H. verus*) implies the existence of both the testicle and the ovary in the same subject, the condition of the external generative organs being of far less moment. In view of the manner in which the sexual glands arise, it is assumable that the indifferent anlage of the glands may undergo subdivision, one portion developing into the male, the other into the female organ, or the same may be accepted for the glands of the opposite sides. Theoretically true sexual duplicity may exist in three forms, bilateral, unilateral, and lateral (Klebs).

A. Bilateral hermaphroditism is the condition in which on both sides a testicle and an ovary exist, separate or partly fused into a composite organ. Almost the only instance of this malformation in man worthy of consideration has been the well-known case described by Heppner. In a two-months' child the external organs were of the masculine type, the penis being imperforate. The internal organs included a uterus, with tubes and ovaries on either side; likewise on each side an apparent testicle. While microscopical examination demonstrated the nature of the ovaries, it failed definitely to establish that the neighboring organs were testicles.

Very recently Garré[121] has reported a case which seems to merit the distinction of being regarded as a trustworthy bilateral true hermaphrodite. The individual, who sought the surgical clinic at Königsberg in Prussia, in addition to malformations of the external sexual organs, presented a hernia-like swelling in the left inguinal region. On opening this, various bodies and cords were found which proved to be testicle, epididymis, vas deferens, ovary, oviduct, and parovarium. The diagnosis was positively confirmed by microscopical investigation, the ovary containing numerous well-formed primary follicles and the testicle characteristic, although somewhat atrophic tissue, but without evidences of spermatogenesis. Digital examination through the rectum discovered on the left side two movable bodies, about the size of a pigeon's egg, together with a cord leading laterally to the urethra. These structures were assumed to be the left ovary and testicle with its duct.

B. Unilateral hermaphroditism is the condition in which on one side is a single sexual gland, on the other two—one testicle and one ovary. Two authentic cases presenting these peculiarities have been observed in the human subject, accepting the one described by Gast[122] as such. The latter was a still-born infant with exstrophy of the bladder. A rudimentary but well-developed penis was perforated by a urethra and lay between cutaneous folds. The internal organs were of the female type. The uterus was bifid and on the right was solid with a sheath-like fibrous extension, from which ran an oviduct with abdominal orifice. The left uterine division was also solid and bore an oviduct with fimbriated extremity. Attached to this was an ovary, showing follicles on microscopical examination; on the same side was a testicle, the size of a pea, from which a gubernaculum extended to the base of the left scrotal sac. Microscopical examination showed this organ to correspond to a testicle in its structure. On the right side no sexual gland could be discovered. The most convincing case, reported by Blanker and Lawrence,[123] occurred in a man. Microscopical examination proved the existence of an ovary and testicle upon one side, with the male gland upon the other.

C. Lateral hermaphroditism, in which one gland, testicle or ovary, exists on each side, is the most frequent variety of true double sex and the group within which the majority of reputed cases of true hermaphroditic malformations fall. Very few such cases, however, are substantiated by trustworthy microscopical examinations, and, therefore, are not beyond challenge. Among the most accurately investigated and convincing cases are those reported by Rudolph,[124] Cramer, Meyer, Klebs,[125] Schmorl,[126] Obolonsky,[127] and Zimmermann.[128]

The case reported by Schmorl was that of an art student, aged twenty-two years, who applied to the surgical clinic in Leipsic for operation to correct hypospadias. The scrotum was rudimentary; on the right side was a small testicle, on the left none. The penis was small and drawn bow-like downward, with uncovered, well-formed but imperforate glans. The groove on the under surface of the penis was 3.2 cm. long, running into a small slit 0.5 cm. in length. An operation to correct the hypospadias and to free the penis was performed, but the patient shortly afterward died. The findings at the autopsy were as follows: Face bearded with hairs about 2 cm. long. Breasts undeveloped, but pubes had hairy growth resembling female. The penis, freed from its adhesions by the operation, measured 5.5 cm. in length with a circumference of 8 cm. To the sides of the penis were genital folds which projected above and grasped the penis between them. Opening into the urethra, 3.5 cm. behind the external orifice, was an aperture into which a probe could be passed for 15 cm. Further examination showed this canal to be a vagina and uterus, the latter consisting of a cervix and body. On the right side were a round ligament, tube and ligament analogous to that of the ovary, all of which extended down to the sexual gland in the right scrotal sac. This gland was shown by microscopical examination to be a testicle, although neither spermatozoa nor vas deferens were found. On the left side a tube ran into the inguinal gland and was continuous with an ovoid body, 5 cm. long and 2 cm. thick, which proved to be chiefly a distended and distorted fimbriated extremity. Histological examination revealed within this body a sexual gland having the characteristics of an ovary, but without ova.

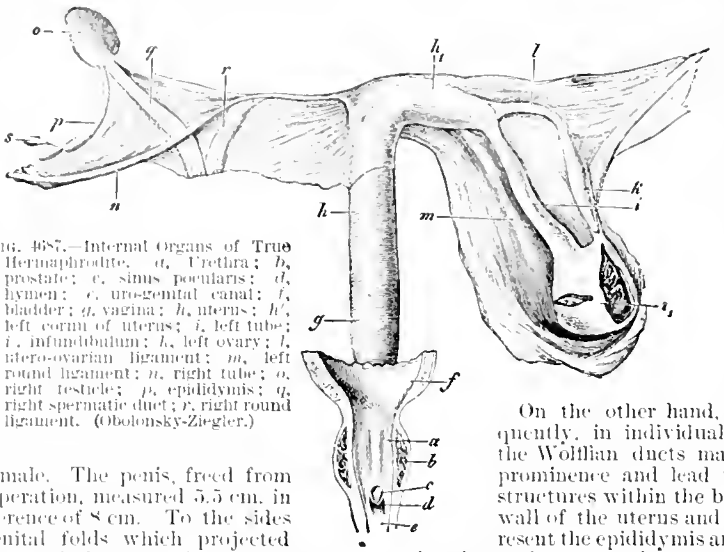

FIG. 4687.—Internal Organs of True Hermaphrodite. *a*, Urethra; *b*, prostate; *c*, sinus pocularis; *d*, hymen; *e*, uro-genital canal; *f*, bladder; *g*, vagina; *h*, uterus; *h′*, left cornu of uterus; *i*, left tube; *i′*, infundibulum; *k*, left ovary; *l*, utero-ovarian ligament; *m*, left round ligament; *n*, right tube; *o*, right testicle; *p*, epididymis; *q*, right spermatic duct; *r*, right round ligament. (Obolonsky-Ziegler.)

The case of Obolonsky was that of a twelve-year-old individual with external organs resembling a female with exceptionally developed clitoris. A well-developed vagina opened into the urethra at the sinus pocularis, guarded by a rudimentary hymen, and led to a unicornate uterus. A prostate was also present. The right broad ligament contained a testicle, an epididymis, and a vas deferens, as well as a rudimentary oviduct and round ligament. The left broad ligament contained an ovary with an ovarian ligament and a well-developed oviduct. Histological examination definitely established the nature of the sexual glands as testicle and ovary.

FALSE HERMAPHRODITISM.—As above pointed out, the crucial test in determining the existence of true double sex is the coexistence of both types of sexual glands; where the presence of these is not established by microscopical examination, the condition is to be regarded as one of pseudohermaphroditism, and the result of aberrant development of the excretory ducts and the external genital organs, which partially represent the characters of both sexes. The most frequent and striking of such malformations are those occurring in individuals of the male sex, in which, in addition to the usual structures, the Müllerian ducts, instead of being rudimentary and atrophic, have undergone unusually extensive development, resulting in the production of an enlarged uterus masculinus, or, in extreme cases, of a more or less well-formed vagina, uterus, and tubes.

In male subjects the external organs may be the seat of aberrant development, in consequence of which the parts assume female characteristics. Thus, the penis may remain rudimentary and resemble a clitoris. Following faulty union of the genital folds hypospadias results, and when extensive the urogenital sinus may open by an orifice resembling a vulva bounded by apparent labia—the ununited scrotal folds, the similarity being sometimes heightened by the absence of testicles in consequence of imperfect descent. Such malformations need not necessarily imply an hermaphroditic condition, although often a part of the defects observed in that connection.

On the other hand, but much less frequently, in individuals of the female sex the Wolffian ducts may assume an undue prominence and lead to the formation of structures within the broad ligament or the wall of the uterus and vagina, which represent the epididymis and vas deferens. Approximation and more or less extensive union of the genital folds, in conjunction with an abnormally large clitoris, may result in closure and obliteration of the vulva to such extent that the urogenital sinus opens beneath the apparent penis by a small aperture resembling a urethra.

Depending upon the predominating sex of the individual, as determined by the character of the sexual gland, pseudohermaphroditism is divided into the *male* and *female* type, in each of which group three varieties are recognized.

Masculine False Hermaphroditism.—I. *Internal*—in which associated with the normal, or nearly so, external male organs are a rudimentary vagina, uterus and, perhaps, tubes. The vagina pierces the prostate and opens into the urethra at the usual position of the sinus pocularis, or uterus masculinus.

II. *External*—in which the outer male organs exhibit faulty development resulting in imperfect fusion of the genital folds and ridges and the consequent resemblance to the female type. The disguise is favored by the general physical characteristics which are often distinctly feminine.

III. *Complete*—in which both internally and externally organs resembling those of the female are present. A more or less well-developed vagina and uterus, possibly also tubes, exist; the vagina opening into a rudimentary urogenital sinus, or short vestibule, into which may lead a groove from the under side of the penis. Less frequently the urethra and vagina open into the urogenital sinus by separate orifices. Very rarely these may be prolonged as canals in an otherwise normal penis, so that this organ possesses apparently double urethræ, the upper tube being the urinary channel, the lower one receiving the sexual ducts.

Of the large number of cases of masculine spurious sex duplicity in the literature the following case, reported by Stroebe,[129] is an interesting example of *pseudohermaphrodismus masculinus internus:* Autopsy on a male subject of sixty-three years showed normal external organs with the exception that the testes were undescended. Within the pelvis an elongated uterus, with well-developed body and fundus (6 cm. broad) lay behind the bladder. On the right side were found an oviduct, a round ligament, and a sexual gland embedded within a broad ligament; on the left the tube was represented by a rudimentary cystic structure that probably was the remains of the Müllerian duct. A sexual gland was also discovered on this side. Microscopical examination showed the sexual glands to be atrophied testicles. The prostate was poorly developed. The uterus opened into the urethra at the sinus pocularis. The course of the vasa deferentia was interesting, since these canals in their lower part lay embedded on either side within the wall of the uterus. The seminal vesicles were abnormal, but the ejaculatory ducts were well developed. These findings point to the simultaneous development of the Wolffian and Müllerian ducts, leading to the production of excretory tubes of both sexes. Failure of the Müllerian ducts to undergo the usual regressive changes was manifestly the immediate cause of the abnormality; the reason for such failure, however, is less evident, although, as pointed out by Stroebe, the disturbing influences must be active at an early period.

Feminine False Hermaphroditism.—This condition is much rarer than in the male. Theoretically it may be subdivided into the three varieties—internal, external, and complete—described in connection with the masculine type.

I. *Internal,* in which, associated with normally formed external organs, the inner are augmented by derivatives of the persistent Wolffian ducts, the homologues of the epididymis and vas deferens, which lie within the broad ligament and the utero-vaginal wall.

II. *External,* in which the external organs assume the appearance of those of the male in consequence of more or less pronounced fusion of the genital folds. The modified parts often resemble a hypospadiac penis with cleft scrotum, the likeness to the latter organ being more striking when, as sometimes happens, the ovary descends through the canal of Nuck into the labium majus. In exceptional instances the urethra may be closed as far forward as the glans clitoridis, in which case the vestibule is no longer open and the external organs resemble those of the male.

III. *Complete,* in which both the internal and external organs present male characteristics. This condition is comparatively very rare. A well-developed prostate and even the homologues of the ejaculatory duct and seminal vesicle have been observed associated with persistent derivatives of the Wolffian ducts.

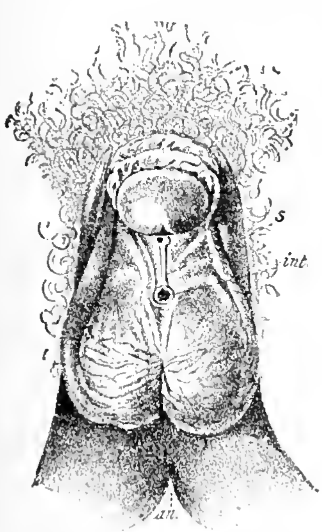

FIG. 4688.—External Organs of Male Pseudohermaphrodite. *s*, Groove; *int*, entrance of uro-genital sinus; *an*, anus. (Günther.)

The determination of the true sex in spurious hermaphroditism by observation upon the living subject is frequently uncertain, especially in view of the possible close resemblances of the external organs to the type opposite the real sex of the individual, as determined by histological examination of the sexual glands. In doubtful cases it is wise to assume that the patient is of the male sex. It should be remembered that spurious menstruation has been observed in masculine false hermaphroditism.

As an example of feminine pseudohermaphroditism established clinically, the case reported by Fitch[130] is of interest. A house servant, aged twenty-eight years, was subjected to examination, when apparently both male and female organs were discovered. The labia majora were of normal size; the labia minora were absent. In place

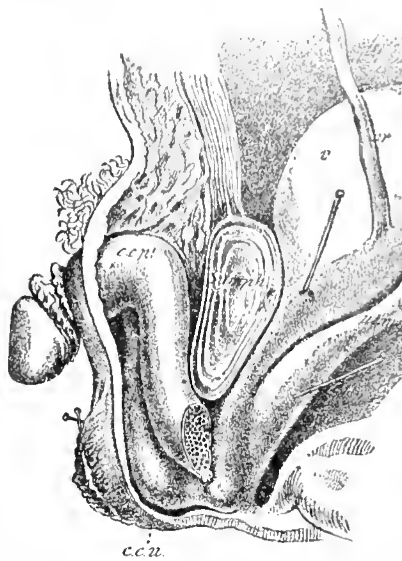

FIG. 4689.—Internal Organs of the Preceding Case. *Symph.*, Symphysis; *v*, bladder; *utm*, uterus masculinus, greatly enlarged; *ur*, ureter; *ccp*, corpus cavernosum; *ccu*, corpus spongiosum. (Günther.)

of the clitoris of usual size was an apparent penis, which, when in erection, measured five and a quarter inches in length and three and three-eighths inches in circumference. The glans was perfect and provided with a urethra. The scrotum was about two inches long and seemingly contained two testicles (?). It was claimed that semen (?) was ejaculated from the urethra. The vagina was spacious and had an os uteri projecting into it. Seven years before the subject had given birth to a normal female infant. Scanty menstruation occurred every three weeks and lasted two days. Sexual gratification was said to be equally distributed between the two sets of organs.

Marchand[131] has described a case of feminine pseudohermaphroditism of exceptional interest as illustrating possible sources of error unless careful histological examination is made of supposed sexual glands. The clitoris was large and but slightly hypospadiac. The vagina opened into the urethra, which was surrounded by a small prostate. Both oviducts were closed at their distal end. Very small ovaries were present in their normal position; that these organs were of this nature was determined by microscopical examination. On the right side the outer border of the broad ligament contained a second body of the size of a well-developed testicle, which proved, however, to be not a sexual gland, but an enlarged accessory suprarenal. Since the presence of these bodies, of very small size, is to be regarded as constant, it is probable that when enlarged they have been mistaken for sexual glands, hence their possible hypertrophy must be borne in mind. Those interested in the literature of the various types of hermaphroditism will find in Taruffi's monograph[132] an exhaustive and systematic review, arranged chronologically.

MALFORMATIONS OF THE EXTREMITIES.—Congenital defects involving the limbs include two chief groups: (1) Those following arrested development, and (2) those occurring in consequence of excessive development, the former resulting in deficiencies, the latter in redundant parts of limbs, especially the digits.

The first appearance of the limb buds in man occurs during the third week of embryonic life, as flattened rounded elevations which project laterally from the body

Teratology.

wall. During the fifth week these growing processes exhibit differentiation into proximal and distal segments, the latter becoming the hands and the feet. By the close of this week the distal segment shows beginning division into digital areas, the upper limbs anticipating in their differentiation the lower by some days. The proximal segment soon becomes subdivided, so that by the sixth week the three chief segments of each limb are evident. The seventh week brings greater distinctness in the separation of the digits and indication of the carpal region of the hand and the corresponding parts of the foot. With the eighth week appear the elbow- and knee joints. The digits, although advanced in development, are still webbed, being connected by a membranous fold of integument. By the ninth week the several divisions of the limbs are present, but not in their definitive proportions. Thus the length of the entire hand is excessive in relation to that of the arm and forearm; likewise, the fingers are too long in proportion to the remaining parts of the hand, and the thumb too long for the other fingers. As already noted, the upper extremity at first leads the lower in its differentiation, but by the ninth week both are of equal length. From this time, however, the lower limb begins to outstrip the arm in its length growth.

The primary shovel-like form of the limb-bud projects at right angle to the body wall; later, with the differentiation into segments, the limbs become folded ventrally and parallel to the sides, stretching obliquely from head tailward. At this stage the future flexor surface of the limb is presented ventrally, the extensor surface dorsally. The preaxial borders of the limbs (radial and tibial, marked by the thumb and great toe) are directed toward the head; conversely the postaxial borders (ulnar and fibular) look tailward. During subsequent growth the upper and lower limbs undergo partial rotation, the arm turning outward and backward, the leg inward and forward. In consequence of these opposite rotations the preaxial border of the upper extremity (thumb and radius) is carried laterally and dorsally, while the corresponding border of the lower limb (great toe and tibia) is turned medianly and anteriorly, these parts of the two extremities being homologous notwithstanding their apparent dissimilarity in the completely developed condition. In their differentiation from the mesodermic tissue composing the early limb, the skeletal segments follow the order of their relations to the trunk, the proximal segments being first defined, the distal ones last.

FIG. 4690.—Amelus. (Ziegler).

Congenital Deficiencies of the Extremities.—These malformations are attributable to causes of several kinds, some of which lead to primary defects, others to secondary. Among the first are primary deficiency in the primitive limb anlage, perhaps inadequate differentiation of the segments and deficient bone formation. The most important causes producing secondary malformations—those modifying limbs which under favorable conditions would develop into normal members—are inadequate intra-uterine space, thereby inducing pressure, and amniotic adhesions and constrictions. Defective development of the extremities is sometimes associated with profound congenital malformations of the nervous system, as spina bifida, involving the nerve trunks supplying the limbs.

The classification of malformations of the extremities suggested by Kümmel,[133] also followed by Kalussner,[134] is the most consistent grouping based upon anatomical data, and to those especially interested in these defects the monographs by the above authors are of particular value. For the purposes of the general reader, however, the clinical classification is more convenient and, while less exact, presents the defects in a useful sequence; it has, therefore, been followed in these pages.

FIG. 4691.—Phocomelus with Double Harelip. (Hirst and Piersol.)

I. *One or more limbs entirely wanting.*

1. *Amelus.* Both upper and lower extremities are absent, while the trunk is usually well developed. The position of the limbs is often indicated by button-like elevations within a funnel-shaped depression.

2. *Abrachius and Apus.* This condition implies the suppression of either the upper or lower limbs, the remaining pair being often well developed.

3. *Monobrachius* and *monopus* result from absence of a single arm or leg, the other limbs, including the mate to the missing member, may be normal.

II. *One or more limbs defective.*

1. *Peromelus.* All the limbs are imperfect, although the causes have not been so radical in their action as to result in complete absence of the extremities. The degree to which the upper and lower limbs are affected often varies, thereby producing the conspicuous malformation known as *phocomelus.* This is distinguished by the rudimentary condition, or complete suppression, of the proximal segment with relatively well-formed hands and feet. According to Kümmel, the most frequent combinations are (*a*) defective development of thigh with relatively well-developed leg and foot; (*b*) defective development of arm or forearm with comparatively well-formed hand. A defect of the upper extremity corresponding to (*a*), that is, defective arm with well-developed forearm and hand, probably does not occur; likewise suppression of the thigh and leg with well-formed foot is very rarely observed.

2. *Perobrachius* and *peropus* are represented by defective development affecting the upper and lower extremity respectively.

III. *One or more limbs abnormally small, although well formed.*

1. *Micromelus,* in which all of the extremities are deficient in size, the diminution, however, being unattended by malformation.

2. *Microbrachius* and *micropus* include such cases in which the abnormality is limited to one or both arms or legs respectively.

IV. *Limb-bones defective or absent.*

Congenital imperfection or absence of the bones of the arm or thigh, forearm or leg, produces a series of ray defects in which malposition and faulty development of the succeeding segments are usually conspicuous, this being particularly so in the hands and feet in conjunction with the absence of the radius and tibia. Defective fibulæ are generally associated with more or less marked shortening of the limb.

V. *Lower limbs fused.*

Sympus, symmelus, or *siren,* as such malformations are variously termed, is distinguished by more or less complete fusion of the lower extremities. The lower end of the trunk is also defective, as evidenced by the malformations of the pelvis and of the external genital organs and excretory passages which are commonly imperfect. The united limbs usually have undergone rotation outward and backward, so that the primary external surfaces become fused. In consequence of such union the lower half of the body forms a conical mass, which may terminate below in a rudimentary single foot (*Sympus monopus*), or two imperfect feet may be present (*S. dipus*). At other times only one or more stunted toes are seen, or all traces of feet are wanting (*S. apus*), the fused extremities ending in a rounded, somewhat elongated apex.

VI. *Hands or feet defective.*

Malformations of the distal limb segments due to defective or arrested development, or *perodactylism,* occur in great variety as to form and detail. In general these abnormalities result from the deficient formation, or entire suppression, of one or more phalanges, combined frequently with fusion of certain digits (*syndactylism*). The variations in these defects are so great that they include all degrees of imperfection, from the scarcely perceptible shortening of a single finger to the presence of mere stunted knob-like digits. One form of malformation, *cleft hand or foot,* is conspicuous on account of the forked appearance due to separation of the marginal digits by a cleft resulting from the imperfect development, or entire absence, of the intervening metacarpal bone or bones and the directly related carpals. The phalanges of the third finger, with the associated metacarpal and carpals, or the corresponding bones of the foot are most frequently wanting, the remaining digits on either side being fused into a marginal ray. In some cases heredity is apparently an important factor in the production of these malformations, as shown in the striking instance of hereditary brachydactyly recorded by Webb,[135] six generations of a family being "short-fingered."

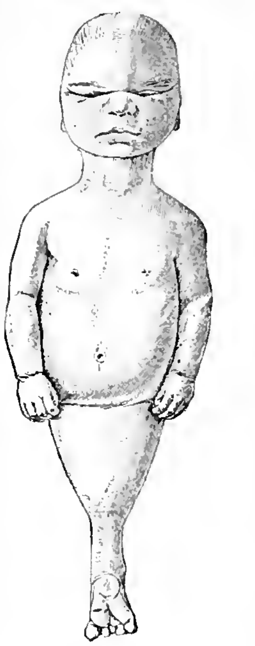

FIG. 4692.—Sympus Dipus. (Ziegler.)

Syndactylism, the congenital union of two or more digits, may be primary or secondary. In the former case the fingers or toes are joined in consequence of imperfect primary differentiation and separation, the digits remaining connected by robust intervening bridges, at times appearing merely as ridges projecting from the fin-like terminal segment. Such malformations are manifestly the result of developmental arrest in consequence either of defective primary formation or of unfavorable influences subjecting the developing digits to unusual pressure. In extreme cases, when all the fingers or toes are blended, the union is usually very intimate, the hand or foot constituting a terminal knob-like mass presenting little resemblance to the normal form. Secondary syndactylism results from more or less extensive union of the digits subsequent to their development. In such cases the connection usually consists of integumentary folds extending for a variable distance from the bases of the digits toward their tips. Exceptionally the union is limited to the latter, the bases remaining free, thereby producing the fenestrated variety of syndactylism.

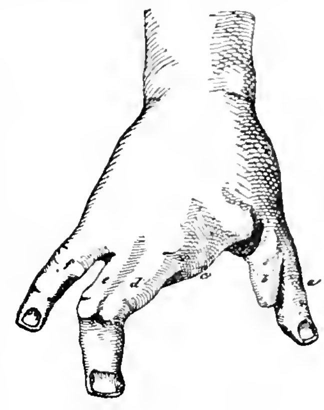

FIG. 4693.—Malformed Hand (Perochirus) with Fusion of Fingers. (Otto.)

Spontaneous or *congenital amputation* of the extremities, effected by constricting cords or bands of amniotic tissue, is responsible for numerous defective limbs. When the ligatures have been insufficient to produce necrosis and complete division of a member, their position is often indicated by marked constrictions and their baneful influence is manifested by the stunted but still attached distal portion of the limb. The latter being compressed within the encircling folds of amnion is unable normally to develop, remains in the fœtal condition, and fails to keep pace with the growth of the more favored parts of the extremity. Spontaneous amputations may involve any part of the extremity, from a part of a single digit to loss of an entire limb. The latter usually ends in a smooth conical stump, while the amputated portion, when separation has occurred at an early period, is commonly not to be found, having undergone complete maceration and disappeared.

Congenital Luxations and Malpositions.—Although the anatomical peculiarities exhibited by osseous and ligamentous structures involved in congenital luxations are usually secondary results and not primary causes of these malformations, the latter call for brief notice in connection with defects of the extremities.

Congenital luxations of the femur are the most important as well as frequent of the prenatal dislocations. They are always secondary and probably due to the effects of malposition of the limbs at a period before the joint was capable of resisting the unusual strain, in consequence of which the femur is forced from its normal socket. Loss of apposition and function result in atrophy and malformation of the femoral head and the acetabulum, the latter being often small and shallow and at times almost wanting. The capsule is stretched and abnormally large. The luxation may be on one or both sides. Similar deformities may affect the knee-, shoulder-, or elbow-joint, although much less frequently.

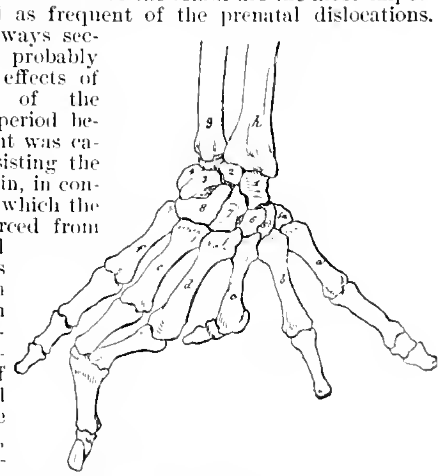

FIG. 4694.—Skeleton of Preceding Deformed Hand. (Otto.)

Congenital malposition of the feet and hands may occur in consequence of faulty position, or undue intra-uterine pressure, without defective development of the skeleton, all types of club-foot or club-hand being observed. In other cases the distortion of the distal segment is associated with defective development of the bones of the forearm or the leg, as of the ulna or radius with talipomanus, or of the tibia with talipes. In the consideration of spina bifida (page 697) attention was called to the frequent occurrence of club-foot with such malformations of the spinal cord. In such cases the talipes results from the loss of balance in the muscular forces acting on the limb in consequence of impairment of the nerve supply to the muscles from the spinal cord.

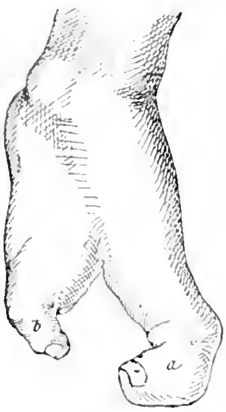

FIG. 4695. Deformed Foot (Peropus). *a, b*, Great and little toes. (Otto.)

The *causes* leading to the various foregoing malformations of all degrees are chiefly those which induce abnormal pressure upon the developing limbs, whether the unfavorable influence be exercised directly by the amnion, or by inadequacy of the space within the uterus. Amniotic attachments or constricting investments are undoubtedly prolific sources of these malformations. Barwell,[136] however, insists that defective limbs are less often the result of constrictions than usually assumed. The histories of many cases, moreover, point strongly to heredity as an additional factor in their production. Ebstein[137] has reported a remarkable example of syndactylism of the fingers and toes through five generations. In other instances it is difficult to account for symmetrical malformations profoundly affecting all the limbs without recognizing an inherent lack of primary development, apart from the dwarfing influences of mechanical forces.

Congenital Redundancies of the Extremities.—These malformations include the frequently observed supernumerary fingers and toes and the rare duplication of the hands or feet. The few instances of reputed doubling of the entire lower limb that have been recorded must be viewed with doubt, since it is highly probable that these cases are to be regarded as double monsters.

FIG. 4696. Skeleton of Preceding Foot. (Otto.)

Polydactylism exhibits all degrees of doubling of the digits, from the scarcely evident partial cleavage of the distal phalanx to the production of a complete two-fold quota of fingers and toes. The presence of ten digits, however, is very exceptional; that of seven or eight is also rare, the most common addition being of only a single supernumerary finger or toe. The position of the latter is usually marginal and about one and one-half times more frequent on the lateral (radial or tibial) than on the median (ulnar or fibular) side. The thumb is oftener doubled than the great toe. The doubling may involve only the phalanges, or the cleavage may begin with the metacarpals or metatarsals. When an entire, comparatively well-formed additional digit is present, it may articulate with the metacarpal or metatarsal of its neighbor, to join directly with the carpal or metacarpal series. More rarely the latter may be also augmented in number to provide special bones and attachments for the extra digit. All possible combinations occur in the relations of the supernumerary parts with the usual digits, especially in conjunction with an associated syndactylism often coincidently present. When very imperfectly developed, the additional finger or toe may be so rudimentary as to be merely a knob-like appendage possessing only integumentary attachment. The extra digits may occur only on a single limb, on both hands or feet, or on all four extremities, although their position is by no means always symmetrical.

The etiology of polydactylism has elicited much discussion, and many theories have been advanced in explanation of these frequent malformations. The assumed causes may be grouped under two headings—external and internal. Foremost among the former are the mechanical impressions due to amniotic cords or folds; among the latter are heredity and excessive differentiation. The presence of opposing amniotic folds is regarded by some authors as the most important factor in producing supernumerary digits which are regarded as arising in consequence of cleavage of the primary anlage, from each portion of which is formed a more or less perfect finger or toe. That in a certain number of cases amniotic folds are probably accountable for the fission resulting in supernumerary digits must be admitted, but the acceptance of such mechanical disturbance as the chief cause of such malformations fails to account for the acknowledged influence of heredity, which is particularly conspicuous in polydactylism. The remarkable case of Muir,[138] in which supernumerary digits were present in five consecutive generations, leaves little doubt as to the importance of these unknown influences in the production of polydactylism.

FIG. 4697.—Polydactylism of Hand. (Ziegler.)

That the presence of amniotic folds is not a necessary condition has been shown by Tornier,[139] who pointed out that polydactylism is particularly frequent in amphibian embryos in which the development of an amnion never takes place. Neither is the assumption convincing that the influence of heredity is not directly exerted upon the limb-anlage, but upon the amnion, in consequence of which a peculiar relation of the amnion to the developing limb is established, resulting in digital fission. It seems scarcely plausible that hereditary influence suffices to arrange amniotic bands with the symmetry necessary to produce supernumerary digits upon all four limbs, as sometimes is the case.

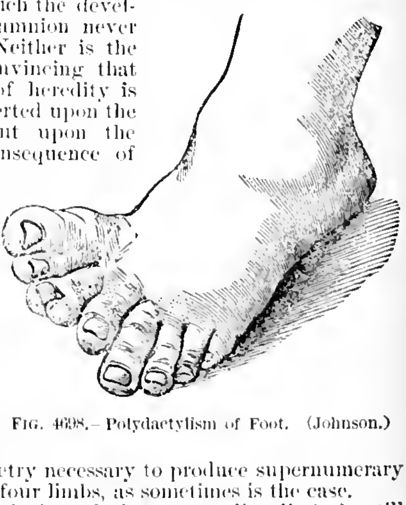

FIG. 4698.—Polydactylism of Foot. (Johnson.)

Since the evolution of the mammalian limb is still shrouded in much uncertainty, we may admit our ignorance concerning the exact rôle played by heredity in producing polydactylism; it is not unreasonable, however, to assume that the impression in some way influences the growth processes which normally result in the differentiation of five digits.

Malformations of the Integument.—The skin is the seat of a variety of congenital abnormalities, some local and others extensive, which depend upon unusual conditions of (1) the epidermis, (2) the cutis and subcutaneous tissue, and (3) the appendages—glands and hair. Since not a few of these congenital abnormalities are caused by pathological lesions more than by errors of development, their consideration falls within the province of dermatology rather than of teratology; such will, therefore, here call for but brief notice.

Abnormalities of the epidermis include more or less general thickening of the epithelial tissue of the integument, which may constitute a horny stratum, several millimetres in thickness, broken only by the furrows caused by the folding and movements of the members of the body. This condition, known as *hyperkeratosis congenita* or diffuse keratosis, is usually characterized by loss of hair and obliteration of sebaceous glands.

Scale-like patches of hypertrophied epidermis distinguish the abnormality termed *ichthyosis congenita*, a condition in which, when extensive, almost the entire body of the fœtus may be covered by irregular areas of greatly thickened epidermis, so that the integument presents a scarred and fissured appearance. When the horny investment of the extremities is very marked, the shell so formed may act as a mechanical restraint to the normal development of the hands and feet, which may, therefore, be defective.

Anomalous pigmentation includes excessive and defective development. The former condition is represented by the smaller or larger colored spots (*nævi pigmentosi*), often very numerous, which may be smooth and unelevated, or raised above the level of the skin and frequently beset with hairs. The color of the pigmented areas varies from a pale to dark brown or black, the epidermis being usually of normal thickness.

Deficient pigmentation or *albinism* of the skin and hair, usually also evident in the iris, choroid, and retina, may be partial or complete. In the latter case the abnormally light-colored skin, white hair, pink irides, and red pupils (due to the vascular reflex through the pigment-free retina and choroid) produce the characteristic appearance of albinos. Partial albinism most frequently affects the hair, genitalia, nipple, and face. The influence of heredity in bringing about the defective development seems questionable, since albinos, although there may be several in one family, are usually the children of ordinarily pigmented individuals, or, indeed, they may be the offspring of negro parents.

Abnormalities of the cutis vera and subcutaneous tissue include the congenital variations affecting the connective tissue of the skin. At times the latter may be of such unnatural density, toughness, and rigidity (*scleroderma congenita*) as to appear tightly drawn, leathery, and unwrinkled. In other cases the same layers may be so loose (*cutis laxa*) that the integument and subcutaneous tissue hang in pendulous folds and admit of unusual extension, recalling the "elastic skin man" of the exhibitions.

In conditions favoring stasis of the venous and lymphatic currents of the subcutaneous tissue, the latter may become the seat of great hypertrophy with enormous distention and infiltration (*elephantiasis congenita*). This condition may affect the integument to such degree that the parts involved lose all resemblance to their normal form. Elephantiasis is frequently observed in acardiac monsters in which the subcutaneous tissue sometimes becomes a misshapen œdematous mass, owing to the infiltration of the areolar tissue.

Dermoid cysts of the skin are not infrequent. These congenital formations are to be distinguished from the true dermoid growths which represent the abortive development of all three germ layers. The ones here under consideration result from abnormal inclusion and isolation of epithelial tissues, which later develop in unusual situations cystic tumors which may attain large size and contain within their walls epidermic deviations, such as hair follicles and sebaceous glands. In accordance with their origin, the favorite seats of such growths are locations in which fusion of the epidermis normally takes place, as along the lines of closure of visceral furrows.

Anomalies of the epidermal derivatives include unusual development of the hair and of the glands.

Congenital *abnormalities of the hair* may be excessive (*hypertrichosis*) or deficient (*hypotrichosis*). The former condition, in which an unnatural profusion occurs in regions ordinarily covered only by fine down, is regarded by Unna and by Brandt[140] as essentially a persistence of the lanugo, or fœtal hair, to the exclusion of the secondary, which commonly later appears. Regarded in this light, hypertrichosis is in fact an arrested development.

The excessive development of hair may be limited (*hypertrichosis localis*), as when confined to some small area, as part of the face in "bearded women," or in individuals possessing hairy nævi or warts; or it may include large tracts or even the entire surface of the body (*hypertrichosis universalis*), as seen in the "wild men" of the museums. In 1883 "Krao," a girl of seven, a native of Indo-China, was exhibited as "Darwin's Missing Link." She was covered with black hair, had prognathic type of face, and possessed extraordinary prehensile powers of lips and feet. Sometimes the hands and feet are uninvolved, as in the case of "Jo-Jo," celebrated as the "Dog-faced Boy." The excessive development of hair commonly takes place after birth, although heredity undoubtedly plays an important rôle in establishing the excessive anlage resulting in this abnormality. Crawford and Yule described a family of Burmah, of which representatives of three generations—father, daughter, and granddaughter—were nearly covered with hair.

Defective development of the hair (*hypotrichosis*) is comparatively infrequent, persistent complete congenital alopecia being decidedly rare. These defects are often associated with deficient formation of the teeth and, sometimes, the nails. A number of instances have been recorded of individuals who have been hairless from birth, even the lanugo having been apparently wanting, although probably partially developed. Heredity here also seems to be an important factor, since in some families congenital alopecia has been noted in successive generations.

Congenital *glandular anomalies* of the skin affect chiefly the sebaceous glands, which may be atrophic or absent, as sometimes seen in keratomous conditions of the epidermis. The cystic growths connected with the sebaceous glands (*atheroma*), formerly regarded as always due to accumulation of secretion, sometimes are probably referable to remains of a congenitally displaced epithelial anlage as a point of origin (Chiari[141]). An excellent presentation of the congenital skin, as well as other diseases affecting the fœtus will be found in Ballantyne's recent work,[142] to which the reader is referred.

Polymastia, the condition of having more than two breasts, is the most important congenital glandular abnormality connected with the integument, since the mammæ in principle are only modified sebaceous glands. Congenital absence of one or both breasts is very rare. Numerical redundancy, on the contrary, is common, supernumerary organs being frequently encountered in both sexes. A distinction, however, must be made between the presence of merely supernumerary nipples (*hyperthelia*) and of additional true milk glands (*hypermastia*), the latter condition being much rarer than the former. The examinations recorded by Bardeleben,[143] including over eleven thousand German soldiers, gave the astonishing results that supernumerary nipples occurred in fourteen per cent., or once in every seven individuals. A percentage so high is probably obtainable only by regarding doubtful cases of pigmented spots as of sufficient significance to be included. Supernumerary nipples seem to be more frequently developed in men than in women; accessory true glands, however, are much more often found in female subjects than in male. The most common situations for the additional nipples are below the position of the normal glands, somewhat nearer the midline; they may occur on one or on both sides, more often, however, on the left side. Other locations of the aberrant nipples generally follow a line passing from the axilla toward the groin; exceptionally they may be upon the back or outer surface of the thigh.

The existence of supernumerary mammary glands is much rarer than of the nipples and is more frequent in women than in men. The positions of such mammæ observed in women include the back, shoulder, axilla, thorax, abdomen, groin, labium majus, and thigh. Trustworthy records show that such organs secreting milk have been located in the axilla, on the chest and the abdomen, in the groin, and on the external surface of the thigh. Hirst [144] refers to a negress of nineteen years who possessed nine mammary glands, five on one side and four on the other. Two of the accessory organs were small and did not secrete; all the others gave milk in large quantities.

The investigations of O. Schultze [145] have shown that the mammary glands are developed along the *milk lines*, ridges of thickened epithelium extending from the dorsal surface, in the vicinity of the fore limbs, ventrally to end in the inguinal region. These observations at once point out the correspondence between the location of the majority of supernumerary nipples and milk glands and the normal formation tracts, the excessive mammæ of the human subject marking unusual development of possible anlages which ordinarily remain quiescent. The influence of heredity seems to be uncertain, although in a number of reported cases both mother and daughter presented polymastia, although the location of the supernumerary mammæ was not identical.

George A. Piersol.

LITERATURE.

The enormous and ever-increasing volume of the literature relating to malformations forbids any attempt to present systematically in these pages even a synopsis of teratological bibliography. Fortunately this is also unnecessary, since those especially interested will find a practically complete bibliography since 1886 in the Anatomischer Anzeiger and the Centralblatt für allgemeine Pathologie, as well as in Schwalbe's "Jahresberichte der Anatomie u. Entwickelungsgeschichte." The "Reports on Teratological Literature" by Windle, which appear from time to time in the Journal of Anatomy and Physiology, are also useful. A valuable general bibliography, including the most important papers, is appended to Marchand's article "Missbildungen" in Eulenburg's "Real-Encyclopädie." For the older literature the reader can consult with advantage Förster, "Die Missbildungen des Menschen," 1861, and Ahlfeld, "Die Missbildungen des Menschen," 1880. A comprehensive list of journal references and monographs, appearing between 1880 and 1901, will be found in Hirst and Piersol's "Human Monstrosities."

The titles given below are only those of papers to which direct reference has been made in the foregoing article.

TERATOMA.—A teratoma is a tumor-like growth characterized essentially by the fact that the tissue-formation of which it is composed does not occur normally in the affected region, or at least not during that period of bodily development in which it presents itself. Such a growth may consist of a single tissue, or may be represented by a cyst (*simple teratoid tumor* or *cyst*); but more frequently it is made of several tissues arising from more than one of the germ layers (*mixed tumor*, "*Mischgeschwulst*"). To the more complicated forms the term teratoma is often applied in a more narrow sense, while those highly complex growths which contain tissues derived from all three of the germ layers are known as *embryoid tumors* or *embryomata*. Teratomata composed of tissue-formations which are out of place in the region where found are known as *heterotopous;* those composed of tissue occurring in a given region at a time when it should not normally be found there are known as *heterochronous*. The tissue-formation composing the teratoma takes its origin either from the anlage of the individual affected (*monogerminal*, *endogenous*, or *autochthonous teratoma*), or from the anlage of a second individual (*bigerminal* or *ectogenous teratoma*, *fœtus in fœtu*). Further, either a sarcomatous or a carcinomatous proliferation may develop within a teratoma, and the growth thereby assume the characteristics of a malignant tumor (*malignant teratoma*).

According to their structure, teratomata may be divided into the following varieties:

Teratomata.
1. Simple teratoid tumors. } Ectodermal. { Dermoid. Epidermoid.
2. Simple teratoid cysts. } Mesodermal. Entodermal.
3. Complex teratomata and teratoid cysts (embryoid tumors and embryomata).
4. Malignant teratomata.

I. Simple Teratoid Tumors.—In this class are placed both heterotopous and heterochronous tissue-formations of simple structure, consisting of but a single variety of tissue, or at most of but a few forms of tissue. For the greater part they consist of heterotopous tissue-proliferations which have their origin in misplaced or persistent fœtal anlage. They may occur in any part of the body, but are found most frequently in certain regions. The most common tumors of this class are the hypernephroma (*kidney, kidney region, liver, etc.*), rhabdomyoma or rhabdomyosarcoma (*kidney, testicles, vas deferens, heart, va-*

gina, cervix, bladder, etc.), chondroma (*salivary glands, mamma, skin, testicles*, etc.), chondromyxoma (*salivary and lachrymal glands, mammæ, testicles*), adenomyxoma (*mamma*), adenosarcoma (*kidney*), adenomyoma (*uterus, broad ligament*), leiomyoma (*kidney*), osteoma (*muscles, skin, mamma*, etc.), lipoma (*meninges*), and the tumor-like formations found along the vertebral column (*coccygeal and lumbosacral lipomata, myolipoma, and the tumors of this region which contain nervous elements*).

The occurrence of tissue-formations in regions in which such tissue-elements are not normally found may be explained by the assumption of a misplacement of tissue anlage, or of tissue at a later stage of development, or of the persistence of undifferentiated cells, which possess the power of producing different forms of tissue. In general, it may be said that the simple teratoid tumors correspond in their structure with the tissue-differentiations occurring normally in the region in which they arise. Every part of the body practically has its corresponding mixed tumor, which in its structure harmonizes with the normal differentiation of the tissues and organs of that region. Thus, for example, the mixed tumors of the salivary and lachrymal glands contain cartilage, bone, myxomatous tissue, connective tissue, epidermis, and glandular tissue, corresponding to their origin from ectodermal and mesenchymal anlage of the head or mouth region. In the mixed tumors of the mamma myxomatous tissue, cartilage, epidermis, and gland tissue are found, corresponding to their origin from ectodermal and mesenchymal or mesodermal anlage. The mixed tumors of the kidney and kidney region which contain striped muscle, cartilage, etc., arise from anlage of the myotome and middle plate. Those of the vagina and cervix arise from the anlage derived from the myotome and sclerotome, or from that portion of the mesoderm lying posterior to the kidney. It is probable that the teratoid growths of this region are dependent upon the development of the Wolffian duct, as they are situated for the greater part in the region of the ducts of Gärtner. The fatty tumors containing epithelial and nervous structures, which are found along the spinal column, chiefly in the lumbo-sacral and coccygeal regions, are due to misplacements of anlage or tissue caused by defective development of the vertebral arches, and are to be classed with the various forms of the malformation known as *spina bifida occulta*. Similar tumors are also found in the cranium. In the changes following a hernial protrusion of the spinal cord and meninges in spina bifida both adipose tissue and striped muscle may be misplaced into the spinal canal. Transposition of adipose tissue, muscle, cartilage, ependymal tissue, and neuroglia is not infrequently seen in these malformations. The lipomata of the cerebral meninges are likewise to be explained in part as due to a transposition of adipose tissue following or attendant upon a defective development of the cranium.

Though the great majority of the simple teratoid tumors are to be regarded as heterotopous proliferations of tissue arising from autochthonous fœtal anlage, it is also possible that some may be due to bigerminal inclusions, in which only one or but a few of the tissues of the parasitic twin persist. The parent cells of the simple teratoid growths in either case remain latent or grow slowly until through some exciting factor a more active proliferation is set up. At first the misplaced anlage increases through a proliferation of undifferentiated cells, but with changing conditions of growth a portion of the cells becomes differentiated, and there are formed mature tissues, which may continue to proliferate in their differentiated form. The causes of active proliferation of latent anlage are unknown; inflammation or irritation or atrophy of the affected part may play the rôle of exciting factor. That the early stages of growth consist in the formation of undifferentiated cells is shown by the fact that the younger portions of the tumor are always composed of such cells. These may predominate to such an extent that the growth resembles a sarcoma (adenosarcoma, rhabdomyosarcoma). Further, the fact that the different tissues constituting the growth (cartilage, striped muscle, etc.) occur in all parts of the tumor can be explained only by the assumption of a later differentiation of cells arising through the proliferation of the undifferentiated cells of the misplaced or persistent anlage. Moreover, the fact that the metastases of the mixed tumors may contain all the tissue found in the primary points to the metastasis of undifferentiated cells, which later become differentiated.

The simple teratoid tumors of the salivary glands, mamma, kidney, uterus, etc., though placed in the same tumor class because of their analogous origin from cells of the ectoderm, mesenchym or mesoderm, nevertheless show great differences in their manner of growth, malignancy, etc. The mixed tumors of the parotid are very slow in development, they produce no metastases, and are relatively benign in character; those of the kidney, uterus, and vagina may grow very rapidly, set up metastases, and assume the character of very malignant tumors. The metastases arise from the transportation of undifferentiated cells from the primary tumor; through the differentiation of these the daughter tumor comes to contain the same tissues as the parent tumor. However, a metastasis of more highly differentiated cells may occur, and the tumor arising from these may present a less complicated structure than the primary. The metastases of the mixed tumors, like those of sarcoma, are hæmatogenous, the lymph glands being rarely involved. The differences in malignancy between the mixed tumors of the salivary glands and those of the kidney cannot at present be explained. The latter present the clinical characteristics of sarcoma, occur more frequently in early life, grow rapidly, and are usually fatal; the former develop in later life, grow slowly, and are only rarely fatal. A secondary carcinomatous or sarcomatous proliferation may, however, develop within the benign teratoid growths of the lachrymal and salivary glands, mamma, etc. The hypernephroma is also frequently the seat of a proliferation so active as to assume clinically the characteristics of malignancy.

All the teratoid tumors are to be regarded as congenital tumors, even when developing very late in life. The persistence of undifferentiated anlage in a latent condition for years has physiological analogues in the late development of the beard, pubic hair, wisdom teeth, etc. Nevertheless, many authors do not accept the congenital origin of these growths and assign to them a development from endothelium, or explain their mixed structure as arising from a metaplasia of other tissues, some going so far as to assume a metaplasia of unstriped muscle into striped, or even of connective tissue into smooth muscle. In some of the simple teratoid tumors, particularly those of the salivary and lachrymal glands, the proliferation of the endothelium is often the predominating feature of the growth, and from a purely structural point of view justifies the designation of *endothelioma* or *myxochondroma endotheliale*, as the case may be. In the consideration of these growths it must be borne in mind, however, that the proliferating endothelium arises from the tumor anlage, and not from the endothelium proper of the region concerned.

2. Simple Teratoid Cysts.—The simple teratoid cysts may be divided into three classes: the *ectodermal, mesodermal*, and *entodermal cysts*.

(*a*) *Ectodermal Cysts*.—These arise from the misplacement or transplantation of ectodermal anlage. They may consist of cavities lined only by stratified squamous epithelium, without hairs or other skin structures (*epidermoid cysts, epidermoids*), or of cysts whose walls contain hairs, glands, subcutaneous fat, etc., presenting all the characteristics of skin (*dermoid cysts, dermoids, dermatocysts*). In the case of the former only epidermal anlages are transplanted; in the case of the latter, embryonal dermal tissue must also be transplanted. These growths are of frequent occurrence; they vary in size from that of a pea to that of an orange. Both epidermoids and dermoids occur chiefly in the skin and subcutaneous tissues as cysts filled with a pultaceous material, resembling atheromata or sebaceous cysts caused by retention of the secretion of sebaceous glands. In the epidermoids the cyst contents consist of desquamated horny cells alone; in the dermoids hairs are found in addition to the desquamated cells. The hairs are of a light or reddish color. Fatty degeneration or liquefaction of the cyst contents may occur, and cholesterin plates may be present in large numbers. At other times the contents are firmer, dry, and present a pearly translucency or lustre. The cyst contents may also become calcified.

Epidermoids.—These are found most frequently in the cranium, neck, thoracic cavity, mediastinum, pelvic cellular tissue, coccygeal region, and perineum, and more rarely in the peritoneal cavity. In the cranium they occur in the meninges or in the hypophysis in the form of the tumors known as *cholesteatomata* or *pearl tumors*. These are spherical or nodular tumors, varying in size from that of a pea to that of an orange, and are distinguished by their glistening satiny white surface. Microscopically, they consist chiefly of thin, non-nucleated, scale-like cells arranged in closely packed laminæ, the central portions of which may present a pultaceous disintegration and enclose plates of cholesterin. According to Boström they are invariably situated at some point upon the pia, which at the site of the growth is covered with stratified squamous cells. These become piled up into a tumor-like mass, and in the course of years form the horny laminæ, which constitute the growth. The neighboring brain tissue and the arachnoid are not concerned in the formation of the horny cells. The dura and arachnoid may cover the tumor. Portions of the cholesteatoma may become separated from the main mass and be misplaced into the brain tissue. At the base of the brain cholesteatomata may be found in the neighborhood of the olfactory lobe, tuber cinereum, corpus callosum, pons, medulla oblongata, cerebellum, and choroid plexus. They are seen but rarely in the meninges of the spinal cord. The intracranial epidermoids arise most probably from epidermal germs which have become misplaced into the anlage of the pia at a very early stage of development. According to Boström, this takes place in the time between the closure of the medullary canal and the separation of the secondary vesicle of the fore-brain from the fore-brain or tween-brain, and the separation of the after-brain vesicle from the hind-brain (fourth to fifth week). The mediastinal dermoids probably arise from disturbances of development of the thymus. Those occurring in the neck arise from remains either of the branchial clefts or of the ductus thyreoglossus. The cholesteatomata of the middle ear may in part be explained as due to misplaced epidermal germs. The epidermoids of the pelvic cellular tissue are the result of epithelial inshoots from the perineum.

Dermoids.—The simple dermoid cysts or dermoids possess walls showing all the characteristics of skin—that is, papillæ, hair follicles, hairs, sweat, and sebaceous glands, and often also subcutaneous fat. The cyst contents are similar to those of the epidermoids, but contain in addition hairs. The dermoids are found in the same regions as the epidermoids, and are to be explained as due to transplantations of dermal anlage at the same time as epidermal.

Both the epidermoids and dermoids may be the seat of development of a squamous-celled cancer. This event occurs most frequently in the neck region (branchiogenic and subcutaneous carcinoma).

(*b*) *Mesodermal and Entodermal Cysts.*—Cysts arising from misplaced or persistent entodermal or mesodermal anlage are of relatively frequent occurrence. They are characterized by a lining of columnar cells, which are often ciliated; and they form cysts varying in size from that of a pinhead to that of a man's head. They are found most frequently in the broad ligament and tubes, less often in the peritoneal cavity, intestine, in the neighborhood of the trachea and bronchi, in the lungs, pleura, tongue, neck, liver, kidneys, etc. They owe their origin to the persistence of fœtal glands or ducts, or to misplaced entodermal or mesodermal epithelial anlage. Those found in the uterine wall, broad ligament, and tubes arise from remains of the Wolffian body and the duct of Gärtner; those of the cervix, portio vaginalis, vagina, and hymen arise from remains of the latter. In the peritoneal cavity and abdominal wall they may arise from snared-off and persistent portions of the intestine (*enterocysts*), or from portions of the urachus (*urachus cysts*). In the liver and kidney they may arise from portions of the gland tubules, which become constricted during the period of development (*adenocysts*). In the neck remains of the internal branchial clefts, in the posterior portion of the tongue the remains of the thyreoglossal duct, or of epithelial buds and glands developing from the same, in the œsophagus and respiratory tract snared-off portions of the intestinal canal or air passages, or remains of the communication between the alimentary tract and air passages, may form the anlage for the development of such cysts. Cysts lined with columnar cells may arise in the central nervous system or its immediate neighborhood (*myelocysts*). These are seen most frequently in the lumbosacral and coccygeal regions. In the abdominal wall cysts lined with columnar cells may arise from remains of the omphalomesenteric duct (*umbilical cysts, omphalomesenteric cysts*).

The origin of entodermal and mesodermal cysts can usually be determined from the anatomical relations and their structure. When the misplacement of the tissue is but slight, and when the anatomical structure still shows clearly the character of the mother tissue the genesis of the growth may be easily determined. The size of these cysts varies from that of a pinhead to that of a man's head. Their clinical importance is dependent upon their location, size, and the character of the secondary changes occurring in them. The cyst wall may become inflamed or undergo degeneration, or through an active epithelial proliferation either adenoma or carcinoma may develop. Adenomata, cystadenomata, and adenomyomata develop frequently from remains of the Wolffian body. In rare cases an adenoma may develop from the remains of the omphalomesenteric duct (*umbilical adenoma*). Adenomata and cylindrical-celled carcinomata may develop from snared-off portions of intestine, or of kidney and liver tubules.

3. Complex Teratoid Cysts and Tumors.—The teratoid cysts and tumors of complicated structure are found in the same regions as the simple teratoid growths, but occur most frequently in the sexual glands, and in the region of the coccyx. Their complicated structure is shown by the presence, either in the cyst wall or in the solid growth, of a great variety of tissues: squamous and columnar epithelium, ciliated epithelium, dermal structures, nerve tissues, cartilage, bone, striped and unstriped muscle, fat tissues, gland tissues, etc. They may also contain tissue of a carcinomatous or sarcomatous nature. The different tissue elements are sometimes of embryonal character. At other times they resemble fully matured tissue. They are sometimes found in orderly arrangement, suggesting the arrangement of tissues and organs found in the normal human body. In many cases, however, there is no definite grouping of tissue elements beyond that of the germ layers, ectodermal tissues being grouped together, mesodermal together, etc. The cysts may be lined with squamous, simple columnar, or ciliated epithelium, and in the first case may contain hair. Teeth and bone are of frequent occurrence in these growths.

Complicated tumors belonging to this class occur in the mouth, nose, and throat, as the so called *hairy polypi*, consisting of polypoid growths covered with hairy skin, and a mass of adipose tissue in which cartilage, bone, teeth, muscle, gland tissue, cysts, etc., are found. In the kidney they occur as solid tumors consisting of sarcomatous tissue containing tubular glands, striped and unstriped muscle, cartilage, bone, etc. Similar tumors are found in the vagina and cervix of young children; they consist chiefly of myxomatous and fibrous tissue, striped and unstriped muscle, and more rarely cartilage and gland tissue. Tumors containing cartilage, bone, muscle, glands, nerve tissue, fibrous, myxomatous, and adipose tissues, ectodermal and entodermal cysts, etc., are found in the region of the coccyx, in the cranium, orbit, mediastinum, abdomen, neck, and lumbo-sacral region. The tissue elements forming these growths may be grouped into rudimentary or fully developed body parts, so that it is possible to recognize portions of the respiratory or intestinal tracts, etc. The complex teratomata of the ovary and testis form the most important and interesting tumors of this class. They occur partly as solid tumors containing multiple cysts, and partly as dermoid cysts, the former being found chiefly in the testis, the latter in the ovary.

Ovarian Dermoids.—The complex dermoids of the ovary occur usually in the form of thick-walled cysts, varying in size from that of a pea to that of a man's head, or even much larger, and containing a fatty pultaceous material, and hair of a light or reddish color. Extending into the cavity of the cyst at some point in its wall there will always be found a polypoid, flat, nodular, or septum-like prominence covered with hairs, and often set with teeth. The latter may arise from a bony formation suggesting the jaw bone. The inner lining of the cyst consists of columnar epithelium, while that of the prominence extending into the cyst consists of skin structures, epidermis, dermis with papillæ, hairs, sweat and sebaceous glands, and beneath these subcutaneous fat. The cyst contents consist of desquamated horny cells undergoing disintegration, cholesterin plates, and hairs. Occasionally the contents are serous or mucoid. The columnar cells lining the remainder of the cyst wall may be absent in part; and the surface so denuded may be covered with granulation tissue, containing many giant cells, which in part surround hairs that have been implanted secondarily into the bare surface. The deeper layers of the wall and of the prominence in particular contain a great variety of tissues, brain, muscle, cartilage, bone, teeth, glands, spaces lined with ciliated columnar epithelium, thyroid tissue, etc. Representatives of all three germ layers are present, the derivatives of the ectoderm and mesoderm being developed to the greatest extent; in particular the skin and its appendages, bone, teeth, and brain substance; while entodermal structures, such as mucous glands, cysts lined with columnar epithelium, etc., are usually developed to a much less degree, and are found only in the deeper portions of the growth. While all ovarian dermoid cysts possess in general the same essential characteristics, the deviations in the character, amount, and relations of the tissues forming the growth are so great that each tumor may be said to have an individuality of its own. This is very clearly shown in the descriptions given of the various cases of ovarian dermoids reported in the literature. They are not to be regarded as simple tumors or cysts, but are composed of two distinct portions—a purely cystic growth and a tumor composed of embryonal elements, any one of which may develop in excess of the others.

In the simplest forms the cyst enclosing the dermoid is of the monolocular variety, although remains of the septa of a previously multilocular cyst may usually be found on close examination. The cystadenoma may predominate over the dermoid, the latter playing such an unimportant part in the development of the tumor in many cases as to constitute only an accidental finding. In the case of a multilocular cyst the dermoid may be located upon the wall of the chief cyst, or upon a septum in the midst of the cystadenoma. Usually, however, the dermoid structures stand out from the wall as a hairy prominence, as described above.

The dermoid portions of the growth may be localized to that part of the cyst wall which is occupied by the prominence, or they may be scattered throughout the wall. In addition to the simple tissue elements various rudimentary organs and structures have been described as occurring in these growths. The parts of the body most frequently found are those of the cephalic end; hence the frequent occurrence in these tumors of brain tissue, maxillary bones, teeth, rudimentary eyes, oral structures, etc. Sections through the dermoid area usually show a groundwork of adipose tissue, through which run connective-tissue trabeculæ containing bone or cartilage. The areas composed of brain tissue may often be recognized by the naked eye. Portions of the skeleton, and such structures as the mammary gland, mouth, eye, etc., may also be recognized by the gross appearances.

In a case reported by Regnier an entire skeleton was found, the right extremities showing complete jointing. Axel-Key describes an ovarian dermoid, in which there were found a head with rudimentary jaws, two lower extremities, and an ossified cranium containing brain substance. In a case observed by Wertheim two extremities were attached to the top of a dermoid containing a well-developed jaw. Graves reports a case in which there was found a head-like extremity with orbital sockets and eyelids with lashes. In a dermoid removed by Thornton there was a head-like process with maxillæ containing teeth, and the stump of an extremity tipped with long nails. Klaussner reported a case containing an entire extremity with jointed skeletal attachment, and fingers with rudimentary nails; Wilms, a case containing an upper jaw with well-formed molar and premolar teeth and a petrous bone; Grechen, one with an entire lateral wall of the cranium; Schramm, a case showing an ossified rib; Küster and Smigrodsky have reported the presence of pelvic bones and ribs; Kapeller, several jointed bones; Pfannenstiel two bones joined by a ball-and-socket joint; and a number of observers have reported the presence of fingers. In some cases the upper and lower jaws have been so well formed as closely to resemble normal specimens; but usually they are so irregular that such a differentiation is impossible.

Teeth are found in the majority of these growths. In some cases several hundred are present. They are sometimes situated within a rudimentary oral cavity, and may project from the alveolar border. Not infrequently they are enclosed within the bone. The dental structure is normal, and all the varieties of teeth may be found; incisors, molars, etc., being arranged upon a rudimentary jaw bone. The absorption of milk teeth and the formation of permanent teeth have also been observed. Such a secondary growth may explain the large number of teeth seen in some cases. Besides the teeth, other structures belonging to the mouth region are seen. Simons has described a parotid gland, Flaischlen a submaxillary, and Mortens and Kroemer have found muscle beneath a mucous membrane, the structure suggesting a rudimentary tongue. In those cases in which there is a more or less well-defined oral cavity there is a sharp line of transition between the epidermis and the oral mucosa. A narrow tube running from the oral cavity in one case was regarded as a rudimentary œsophagus. Thyroid tissue has been found in a number of cases.

Brain tissue may be present in very large amounts. In some cases cerebral hemispheres, gyri, cerebral fissures, and pia mater have been seen. All stages from the earliest rudiments to the fully-developed type are seen. The brain is usually enclosed in a fibrous envelope consisting of a single or several layers of connective tissue. The outer layers contain a great deal of elastic tissue, and often cartilaginous and osseous areas. In some cases it is possible to differentiate between the dura and the pia. In the majority of cases the most striking evidence of the presence of rudiments of the brain is afforded by the retinal pigment, which is of very common occurrence in these tumors. In a number of cases more or less completely developed optical vesicles have been found in the shape of bilateral pedunculated appendages. Born has described open spaces and bony structures lying posterior to the optical vesicle, and he considers them to be the rudiments of the ear. The brain tissue is sometimes differentiated into cortical and medullary layers, the former containing typical pyramidal cells. In some cases cranial nerves and ganglia were found which were regarded as corresponding to the optic and trigeminus. Sympathetic ganglia are frequently present. Kroemer observed a sympathetic plexus within the muscular wall of a rudimentary intestine. In a case reported by Kappeler a complete medullary tube with central canal, anterior commissure, longitudinal sinus, and intervertebral ganglia enclosed in a vertebra were found.

The presence of mammary gland tissue has been noted by several observers. Of these cases the most remarkable is the one described by Yamagiva, who regarded the adenocarcinomatous changes found in a teratoma of the ovary as primary in a nipple-like growth of mammary gland tissue which presented itself on the inner surface of a large dermoid cyst.

Of entodermal tissues, there have been found rudimentary œsophagus, trachea, larynx, lungs, nasal and pharyngeal cavities. In all of these an abundance of ciliated epithelium was present. Portions of the gastro-intestinal tract lined with cylindrical epithelium containing goblet cells have also been observed. Typical villi, intestinal glands, a characteristic muscular wall, typical Peyer's patches, and solitary follicles were present. In one case described by Pommer there was a cæcum-like intestine with a vermiform appendix. Liver and pancreatic tissues have not yet been observed.

Of mesodermal tissues, there have been observed the various connective tissues, cartilage, bone, marrow, striped and unstriped muscle, lymph glands, lymph- and blood-vessels. Kroemer found a rudimentary uterus, in which the branching glands of the cervix and the tubular fundal glands were easily differentiated. Katsurada has recently reported the presence of heart muscle. Kidney tissue has not yet been observed.

Solid Teratomata of the Ovary.—The solid mixed tumors of the ovary are somewhat more rare than the dermoid cysts. They contain the same tissues found in the latter, but differ from these in that the tissues show a less orderly arrangement, and, as a rule, a more rudimentary character. They may contain numerous small dermoid cysts. Inasmuch as transition stages may be found between the dermoids and the solid teratomata, the two forms are to be classed together as closely related genetically. In some cases the solid character of the growth may be due to adenomatous, carcinomatous, or sarcomatous proliferation of the tissues of a dermoid. There is, however, no very logical reason for separating the so-called dermoid from the solid form.

The ovary may be completely destroyed by these tumors, but in the majority of cases some remains of its tissues are preserved. The dermoids and solid teratomata of the ovary are observed most frequently in early adult life, but may occur in children. They not infrequently develop at puberty. Several dermoids may in very rare cases be found in the same ovary. They occur on both sides in about fifteen per cent. of the cases. Carcinoma or sarcoma may develop in these growths, and secondary inflammation, degeneration, etc., may also take place.

Since the most characteristic feature of ovarian dermoids and solid teratomata is the fact that they contain tissues derived from all three of the germ layers, their structure gives the impression of a rudimentary embryo, and they have been accordingly classed as *embryomata*. By some writers the term embryoma is applied only to the dermoids, while the solid teratomata, because of their lack of any structural organization approaching that of the human embryo, are designated *embryoid tumors*. The presence of tissues derived from all three of the germ layers can be explained only by the assumption of a development from an ovum. According to Wilms and others, a *parthenogenetic development of an unfertilized ovum* may be assumed. No absolute proof of this hypothesis exists at present, and nothing is known concerning parthenogenesis in mammalian ova. It does not seem probable that the development of these tumors is due to parthenogenesis, since the latter is a normal process in lower animals and plants, having for its aim the propagation of the species, and the development of these tumors can be regarded only as a pathological process, in which the growth and differentiation of tissues and organs are atypical and apparently without a definite law. In favor of the ovulogenous theory of origin is an observation made by Lee in one case in which the minute dermoid maintained the same relationship to the follicular cavity as that of the ovum to the follicle. Steinlin has also described a case in which a small dermoid remained as an intrafollicular growth connected with the follicle wall by a delicate vascularized pedicle. Sutton made a similar observation in the case of a dermoid cyst in the ovary of a horse, and Kroemer was also able to establish a similar relationship between the dermoid and the follicle in two cases in the human being. From these observations it would appear that the epidermal covering of the dermoid is derived from the ectoderm of the ovum. The dermoid is sometimes surrounded by a membrane resembling amnion.

Bonnet, on the other hand, regards it as much more probable that the complex ovarian teratomata arise from *one or more blastomeres which during the early stages of development of a fertilized ovum* are delayed in division, and later give rise to an independent formation containing elements of all three germ layers; or that a *fertilized polar body* finds its way between the blastomeres of a developing ovum, and later develops within the embryo. The fertilization of the polar body has been demonstrated in vertebrates. The first assumption seems more probable, and the ovarian embryomata and embryoid tumors may, therefore, be regarded as *rudimentary unioval twin malformations*, and are to be placed in the same category with the fœtal inclusions found in other organs. The fact that the ovary is the favorite seat of such growths may be dependent upon the fact that the urogenital anlage forms relatively such a large part of the embryonal anlage, or that the blastomeres from which the sexual glands arise take on more easily than others an especial development which leads to the formation of a rudimentary twin. Duplication of the embryonic area, or of the primitive streak or medullary groove, with subsequent inclusion of one twin (parasite) by the autosite might explain the formation of some of the ovarian embryomata. Wilms, Pfannenstiel, and Kroemer are the chief advocates of the ovulogenous origin of these tumors. Bandler, on the other hand, has recently attempted to prove their congenital origin, holding that they arise from derivatives of the ectoderm, which have a mesodermal stroma, viz., the Wolffian bodies and ducts (according to Spee, the epithelium of the Wolffian body and duct comes from the ectoderm). Bandler, therefore, holds that the ovarian dermoids and cystadenomata have a closely related histogenesis. His attempt to refer the embryomata of the sexual glands to ectodermal implantations occurring accidentally during the development of the urogenital system cannot be regarded as successful, since the anlage of many structures found in these tumors (teeth, thyroid, eye, etc.) cannot possibly be located in the urogenital anlage. There is an increasing number of writers who accept the ovulogenous origin, but the majority of these reject the hypothesis of parthenogenesis. The etiology of the anomalous development of the ovum is not yet known.

Complex Teratomata of the Testicle.—Complex tumors of the character of the ovarian dermoids have been found in the testicles, in the case of both children and adults, but are of rare occurrence. Their structure is essentially the same as that of the ovarian tumors. Solid complex teratomata are of much more common occurrence in the testicles. They may be congenital, but are found more frequently in early adult life. In structure they differ from the complex ovarian teratomata in that they do not contain so great a variety of tissues, and that these are not grouped so as to form easily recognized organs or systems. The tissue elements, moreover, are more embryonal in character and attain only a very rudimentary development. Ectodermal tissue is present usually in but scanty amounts, and is represented by pigmented epithelium or by small groups of cells showing cornification. In some tumors it may be entirely absent, or at least cannot be demonstrated. The cysts are lined usually by entodermal epithelium, but the character of the epithelium may vary in one and the same cyst. Simple cubical and cylindrical epithelium, either with or without cilia, stratified cylindrical ciliated epithelium and pigmented epithelium may be found. Mucous glands may also be present. Of the connective-tissue elements, fibrous tissue, myxomatous tissue, cartilage, bone, striped and unstriped muscle, are most frequently present. All these present a more cellular and embryonal character than the tissues found in the ovarian teratomata. As a rule, some one of the tissues predominates, and a carcinomatous or sarcomatous proliferation occurs in the majority; hence the teratomata of the testis have been reported under a great variety of names: *adenochondroma, adenocystoma, chondrosarcoma, malignant chondroma, rhabdomyosarcoma, adenomyosarcoma, cystosarcoma, cystocarcinoma, adenocarcinoma, myxosarcoma*, etc. In some cases an endothelial or perithelial proliferation predominates, and the tumor assumes the character of an *endothelioma* or a *perithelioma*. Syncytial like formations have also been described as occurring in these growths. In some cases the formation of cysts with fluid or mucoid contents is the most striking feature of the tumor; in other cases the growth may be cystic only in part, while in other cases it is solid throughout. They are often of very rapid growth, and those in which carcinomatous or sarcomatous proliferation occurs are of very malignant character, giving rise to numerous metastases throughout the peritoneum, retroperitoneal glands, lungs, etc. The metastasis in the majority of cases is hæmatogenous, like that of sarcoma. To what extent the teratomata of the testicle are to be classed with the embryomata as of ovulogenous origin, or to what extent they are due to tissue-implantations, cannot at present be determined. Those containing tissues derived from all three of the germ layers may be classed with the embryomata or embryoid tumors; those consisting of single tissue-formations may be explained by the assumption of a tissue-transplantation or inclusion.

The complex teratoid cysts and solid teratomata of other regions, as well as those of the sexual glands, are in many instances to be regarded as local disturbances of development, due to a misplacement or separation by constriction of tissue anlage or tissue within a single individual (*monogerminal tissue-implantation, autochthonous teratoma*). The hairy polypi of the throat and mouth cavity, the cystic or solid teratomata at the base of the skull or in the hypophysis may be explained as due to inclusions of ectoderm. The presence of cartilage and mucous glands in the mediastinal teratomata may be explained by the proximity of the trachea. The teratoid mixed tumors of the cervix and vagina are probably due to inclusions of the myotome or sclerotome, and to malformations in the development of the Wolffian duct; those of the kidney are due to proliferation of remains of the Wolffian body, and to inclusions of the myotome; those of the lumbo sacral and coccygeal regions are due to proliferations of remains of the neuro-enteric canal, hind gut, and medullary canal, in association with ectodermal and mesodermal inclusions.

There is, however, another possibility of origin for these tumors—they may arise from a rudimentary twin (bigerminal implantation). Such an explanation receives support when the teratoma in question contains fully developed or rudimentary organs or body parts, or tissue-formations that cannot be explained by the misplacement of tissue of a single fœtus. The complex teratomata at the base of the skull, in the sacral region, in the mediastinum, and in the abdominal region are regarded by the majority of investigators as bigerminal implantations. Such teratoid tumors are then to be interpreted as parasitic twin malformations, and are to be classed with the double monsters (see *Teratology*). All possible transition forms exist between those composed of rudimentary tissue-elements and the double monsters with symmetrically developed twins. In those cases in which partly or fully developed extremities or organs lie within the tumor mass or cyst the diagnosis of bigerminal inclusion is clear, but in the case of a more rudimentary development of tissues which are not arranged in an orderly manner it is not always possible to differentiate between monogerminal and bigerminal inclusions.

Malignant Teratoma (*Teratoma malignum*).—Malignant changes may take place in any form of teratoid tumor or cyst, the simple forms as well as the more complex, but are of more common occurrence in the latter. Of the simple teratomata the epidermoids and dermoids most frequently take on a malignant activity of growth (*branchiogenic* and *subcutaneous carcinoma*), although ectodermal inclusions in any part of the body may be the starting-point for an epitheliomatous growth. The tumors of the kidney, vagina, and cervix that contain striped muscle and myxomatous tissue usually behave as sarcomata. The mixed tumors of the salivary and lachrymal glands become malignant much more rarely. Since the great majority of other forms of teratoid tumors are usually benign, the term malignant teratoma is more appropriately applied to the malignant embryomata and embryoid tumors. The complex dermoids are less frequently malignant, or at least but relatively few cases of carcinomatous or sarcomatous dermoid of the ovary have been reported. Yamagiva has reported a unique case of a dermoid of the ovary, showing adenocarcinomatous changes. The patient was a woman sixty-three years old, dying from the effects of a large ovarian tumor, which was in part composed of solid mixed tissues and cysts, and partly dermoid. The adenocarcinomatous changes present he regarded as primary in a mammary gland which presented itself on the inner surface of the large dermoid cyst. Metastases were present in the retroperitoneal, mesenteric, and right supraclavicular glands. To Bierman belongs the credit of having recorded the first case of epidermal cancer arising from the epidermal lining of the cyst cavity. Similar cases have been reported by Krukenberg, Clark, and others. The majority of the cases have been in women at or near the menopause. The metastases are found chiefly upon the peritoneum. Of much greater frequency is the development of carcinoma or sarcomatous changes in the solid complex teratomata of the ovary, testis, and mediastinum. In the case of the malignant teratomata of the testis the metastases may present the appearances of cystocarcinoma, cystosarcoma, chondrosarcoma, chondrocarcinoma, myosarcoma, myxosarcoma, endothelioma, etc. Occasionally the metastases show differences of structure, or may present a combination of tissue elements. This may be explained by the metastasis of undifferentiated cells. In some cases the tumor presents the appearance of a mixture of sarcomatous and carcinomatous proliferation ("*sarcocarcinoma*"). The distribution of the metastases varies somewhat with the character of the malignant changes. In the case of adeno- or cystocarcinoma of either an ovarian or a testicular teratoma the metastases are found chiefly upon the peritoneum; in other cases the metastases are usually hæmatogenous, and are found chiefly in the lungs.

Treatment.—The fact that a large class of tumors is composed of tissue-formations resembling those of the normal body, and derived from misplaced anlage or tissue, or from fœtal inclusions, throws important light upon the treatment. Since such tumors are manifestly not of parasitic origin, their treatment by toxins, antitoxins, Roentgen rays, etc., is naturally contraindicated. Only those toxins would destroy the mixed tumors which would at the same time destroy the normal tissues. The treatment is purely operative, and even here the knowledge of the mixed nature of the tumor is of great importance in modifying the operation. The mixed tumors of the mamma do not set up metastases in the axillary glands; and since the encapsulated mixed tumors in general usually give rise to hæmatogenous metastases, and not lymphogenous, a more conservative operation may be carried out than in the case of carcinoma. In the case of the tumors of the testis the greater tendency to malignancy with the rapid setting up of metastases in the peritoneum in the case of carcinomatous change, and in the lungs in the case of sarcomatous or endotheliomatous changes, speak for the necessity of early operation. (See also *Teratology*, *Hypernephroma*, etc.) *Aldred Scott Warthin.*

TEREBENE.—Terebene, $C_{10}H_{16}$, is a liquid hydrocarbon, obtainable by the action of strong sulphuric acid on oil of turpentine. It is a colorless, mobile fluid, of a pleasant pine-wood odor and taste, free from the acridity of oil of turpentine. It is insoluble in water, but dissolves in an equal measure of alcohol.

Under the name *Terebenum*, Terebene, the United States Pharmacopœia makes official "a liquid consisting chiefly of pinene, and containing not more than very small proportions of terpinene and dipentene." Terebene should be kept in well-stoppered bottles and in a cool dark place.

Terebene seems to affect the human system like a mild oil of turpentine. It has been taken in so large quantities as a teaspoonful every four hours, continued for a week, without untoward effects; but such quantities are unsafe. Under the influence of the medicine the urine acquires an odor as of violets, and may increase slightly in quantity. Medicinally, terebene has been found of service for the alleviation of cough and dyspnœa from respiratory disease, and of dyspepsia with flatulence and acidity. The drug is commonly given in doses of ten drops, or thereabouts, in emulsion or in capsules. It is not at all unpleasant to take, clear, washed down with a small sip of water. In respiratory affections the vapor of terebene may be inhaled in addition to the internal administration. *Edward Curtis.*

TERPIN HYDRATE.—When a mixture of turpentine oil and water is permitted to stand, crystals of terpin hydrate, $C_{10}H_{18}(OH_2) + OH_2$, often deposit. For artificial preparation of the crystals in quantity, a mixture is made of oil of turpentine, nitric acid, and alcohol, which is set aside in shallow vessels for crystallization to occur. The substance is official in the United States Pharmacopœia under the title *Terpini Hydras*, Terpin Hydrate. Terpin hydrate is in the form of colorless, rhombic crystals, practically devoid of odor and taste. It dissolves in about 250 parts of cold water and in 32 parts of boiling water; in 10 parts of cold alcohol and in 2 parts of boiling alcohol. The drug is claimed to possess the medicinal "expectorant" virtues of the terebinthinates, while free from the deranging influence of the class. It may be administered in doses ranging from 0.20 gm. to 0.65 gm. (from gr. iij. to x.), given a number of times daily, in emulsion or pill. *Edward Curtis.*

TERPINOL is an oily liquid of hyacinthine taste, obtained by distilling terpin hydrate with dilute sulphuric acid. It consists of *terpineol*, $C_{10}H_{17}OH$, mixed with three terpenes, $C_{10}H_{16}$, and is insoluble in water and soluble in alcohol and ether. Lazarus employs it like terpin hydrate as a bronchial stimulant and antiseptic in dose of 0.3 c.c. (♏ v.). Janowsky gives it in hæmoptysis, three drops frequently repeated. It is sometimes added to iodoform as a deodorizer. Under the name of "stomatol," a mixture of terpinol, soap, alcohol, and aromatics, is sold as a mouth wash and general antiseptic and deodorizer. *W. A. Bastedo.*

TETANUS.—(Synonyms: Trismus, Lockjaw.) Tetanus is an acute infectious disease caused by inoculation with the tetanus bacillus, and characterized by tonic spasm of certain muscles, sometimes by clonic spasms as well. The more severe acute cases usually end fatally in from one to seven days. Mild cases, sometimes called chronic, may last for some weeks and end in recovery.

For a full description of the tetanus bacillus the reader is referred to the article on *Bacteria*, p. 698, vol. i., of this Handbook. It must be remembered that this organism is almost everywhere to be found in garden and field soil, in the street dirt of cities, about manure piles, and in the foul mud of marshes and river beds. The reason that more people are not infected by this well-nigh omnipresent germ is because it is anaërobic and quickly killed by sunlight.

Etiology.—For the growth of the tetanus bacillus in or upon the human body it is essential that there be a wound upon which the bacillus shall be received. If the wound be septic or becomes septic, it offers the best soil for the growth of this bacillus, since the ordinary septic organisms absorb all the oxygen present and so produce the anaërobic conditions necessary for the life of the tetanus bacillus. It is doubtful whether any truly aseptic wound was ever the seat of tetanus infection. There need, however, be no gross solution of continuity in order for the development of the tetanus bacillus, since it has been found at the site of a severe blow or bruise.

Pathology.—There are no definite anatomical changes as yet known to belong to this disease. The bacillus is to be found in or near the infected wound, although the local lesion may not be prominent and the wound may have healed. A few observations are on record in which the bacilli were found on the *pia mater* and arachnoid of the spinal cord. In the brain and cord are found perivascular exudation, congestion, and granular degeneration of nerve cells. The local infection with the tetanus bacillus seems to produce a toxin, which, when it reaches the brain and spinal cord, causes symptoms similar to those of strychnine poisoning. A substance called tetanin has been isolated from tetanus cultures; it is said to be four hundred times more poisonous than strychnine.

Symptoms.—The period of incubation varies considerably. In temperate climates it is likely to be two weeks, sometimes three. In tropical climates, or in localities where the disease is especially virulent, there may be as short a period as one day. The onset is gradual, with soreness and stiffness in the muscles of the neck and jaw, until at the end of from one to three days the mouth cannot be opened (trismus or lockjaw). This muscular rigidity or tonic spasm extends to the muscles of the face and trunk, in less degree to those of the legs, while the arms are often exempt. The contraction of the face muscles so draws up the corners of the mouth as to produce a fixed grin, the so-called *risus sardonicus*. The abdominal and chest muscles become board-like in their rigidity, greatly impeding respiration. The body is often arched backward (opisthotonos), or it may be fixed in some other position. An aggravation of the spasms, which may have somewhat relaxed, is produced by any sudden stimulant, such as a loud noise, a draught of cold air, or an attempted movement. These spasms are always tonic or continuous, never intermittent. Some patients complain of great pain connected with the spasms, others of none whatever. The mind usually remains clear throughout. The temperature in mild cases may be but little raised. Usually, however, it reaches 104° or 105° F., sometimes as much as 108° during life, and it often rises a degree or two after death. The body is bathed in sweat, the urine is scanty and often albuminous. Death may occur in twenty-four hours from the outbreak of the disease, or not for four or five days.

Chronic tetanus usually begins a longer time after infection, is milder in form, often without fever, and the spasmodic contractions may be limited to the part of the body near the wound, although they may also be general. This form may last for two or three weeks and is much less fatal. A variety of the chronic form, called by the Germans *Kopftetanus*, follows injuries about the distribution of the cranial nerves, especially those of the supra-orbital margin. It is marked by trismus with facial paralysis, although both tonic and clonic spasms may occur in other parts of the body.

Diagnosis.—The history of a poisoned wound, especially a dirty, punctured wound of the foot or hand, is an important factor in the diagnosis. Mild forms of trismus, with none of the other symptoms of tetanus, sometimes follow dental irritation, as from a carious tooth or an unerupted wisdom tooth. Apparent trismus may also be hysterical. Tetanus may be distinguished from strychnine poisoning by the fact that in the former the onset is comparatively gradual, while in strychnine poisoning it is sudden. In tetanus the muscles are continuously rigid, even during the intervals of spasm, while in strychnine poisoning they are relaxed during the interval. Trismus is always present in tetanus, not so after strychnine. The arms are always involved in strychnine poisoning, very rarely in tetanus. Hydrophobia is to be distinguished from tetanus by the character of the spasms, which are clonic in the former, tonic in the latter. In hydrophobia the muscles of respiration, and especially those of deglutition, are early and prominently involved; not so in tetanus. In hydrophobia there is no trismus nor opisthotonos. The demonstration of the presence of the tetanus bacillus in a suspected wound would be conclusive evidence of the character of the malady.

Prognosis.—This is very unfavorable. From seventy to ninety per cent. of all cases are fatal. This, at least, has been the record of the past. Under more recent methods of treatment (antitoxin and carbolic-acid injections) better results are claimed in some countries. Thus, at a recent congress of surgery Dr. Valles, of Lyons, France, had collected 373 cases with 145 deaths, or 39 per cent. There is no doubt but that the very acute cases are almost uniformly fatal, and that a short period of incubation is proportionately dangerous. In Rose and Carless' "Manual of Surgery" (William Wood & Co., 1901) the statement is made that if the period of incubation is under ten days only 4 per cent. recover; if it lasts from eleven to fifteen days, 27 per cent. recover; while if the outbreak is delayed for fifteen to twenty days, 45 per cent. live.

Treatment.—The preventive treatment consists, first, of thorough antisepsis applied to wounds, and the worse the sanitary conditions under which patients are found the more radical should be this antisepsis. This means the thorough laying open and cauterization of recent wounds, with pure carbolic acid, for instance, or the excision of cicatrices of longer standing, with cauterization of the site. The immediate prophylactic injection of 10 to 20 c.c. of Behring's tetanus antitoxin, in case of the existence of "a suspicious wound," and the repetition of this treatment every day or every other day for a week or ten days have been recently advocated in Germany. It is evident that any amount of good results can be claimed from such treatment, when it is not certain that the wound is infected with tetanus. The best that can be said for it is that it is safe.

After the appearance of the general symptoms of tetanus three methods of treatment are before us, viz.: the old treatment, with absolute quiet and sedatives; second, the antitoxin treatment; and third, the Bacelli treatment, with hypodermic injections of carbolic acid. In view of the dire nature of the disorder and the unsatisfactory results of all treatment, the probabilities are that the wide-awake practitioner will avail himself of all three of these methods at once. The old method of treatment consists in the isolation of the patient, so as to secure absolute quiet, and the free administration of chloral and the bromides or of hypodermic morphine, enough being used to insure quiet rest. Chloroform by inhalation is also used to control spasms, or to permit of feeding by the stomach tube two or three times a day. The *antitoxin treatment*, as ordinarily practised, consists in the subcutaneous injection of some one of the various preparations of tetanus antitoxin serum. The original serum is that of Behring, of which 20 to 30 c.c. should be injected every five or six hours. Of Behring's dried serum 5–10 gm., dissolved in distilled water, is used. Various manufacturing houses in this country prepare these antitoxin serums, and they are also prepared by certain of our state boards of health. It is of the utmost importance that the article should be obtained from a reliable source, and that it should be reasonably fresh.

Much disappointment has followed the use of tetanus antitoxin. Even early prophylactic treatment by this method, vigorously pushed, has often failed. And yet there is no doubt that when the statistics of large numbers of cases are studied a decided lowering of the mortality can be recognized. Large doses, begun early and used thoroughly and persistently, will often accomplish the desired result.

Of late years the opinion has been gaining ground that subcutaneous injections of antitetanus serum are merely preventive of further general infection; that when the first symptoms of tetanus appear the nerve centres are already gravely poisoned, and that the best results must be sought by bringing the antitoxin into immediate contact with those nerve centres. Hence the employment of *intracerebral injections* of antitetanus serum. Rose and Carless (*opus cit.*) thus describe the procedure: "The injection is made through the dura mater into the posterior portion of the second frontal convolution on each side; 2.5 c.c. of the dried serum dissolved in 5 c.c. of sterilized water are injected very slowly, and this may be repeated several times, if an interval of a few days be allowed to elapse between two consecutive injections. The point selected is placed midway between the external angular process of the frontal bone and the centre point of the line between the root of the nose and the external occipital protuberance. A small trephine may be applied here, or simply a hole drilled through the skull sufficient to allow of the introduction of a syringe, which is pushed about two inches deep into the brain. Of course the strictest antisepsis is essential. Probably it will be found wise to restrict this method to the treatment of the worst cases, and it must be augmented by subcutaneous injections and other subsidiary measures."

Some brilliant results from this method have been reported. The greatest number of cases of intracerebral injection which the writer has been able to find tabulated is 233, with 96 recoveries and 137 deaths, giving a mortality of 58.7 per cent.

Spinal subarachnoid injections have also been employed and good results reported, although the total number of cases recorded is still too small to permit of positive conclusions. Five to ten cubic centimetres of cerebro-spinal fluid are withdrawn and 10–20 c.c. of antitoxin injected very slowly under weak pressure.

The *carbolic-acid treatment*, also called the Bacelli treatment, after the name of its distinguished originator, consists in the subcutaneous injection of a two-per-cent. solution of carbolic acid, at intervals of from two to four hours, in such quantity that not less than three grains of the acid is used the first day. As much as six or eight grains per diem may be employed, according to the urgency of the case. No poisonous effects have been noted and excellent results have been claimed, especially in Italy. It is believed by some observers that tetanus is not so virulent in Italy as in some other countries.

As previously stated, there is no reason why the various methods of treatment above given may not all be employed at the same time. The writer recently saw a case of tetanus following the usual punctured wound of the foot from stepping on a nail. Tetanus developed on the fifth day, with trismus, opisthotonos, and violent periodical spasms. Antitetanus serum (Parke, Davis & Co.'s) was injected every six hours, carbolic-acid injections were used to the extent of five grains a day, and the periodical spasms were controlled by the hypodermic use of hyoscine hydrobromate, gr. $\frac{1}{50}$ *pro re nata*. The disease yielded on the fourth day so as to permit of the patient's drinking from a cup. An individual case, such as this, proves nothing, and it is only mentioned as an example of the combined treatment.

As this article goes to press the writer learns of certain experiments on animals made by Prof. A. P. Matthews, of Chicago, which may in the near future give us the means of successfully combating the toxins of tetanus as well as other toxins. It appears that Profs. J. Loeb and A. P. Matthews have for some time been experimenting in the production of a saline infusion which should cause stimulation of the cells as well as produce cell catharsis and diuresis. Having attained this object, so far as the washing out of ordinary metabolic bodies is concerned, and wishing to ascertain whether bacterial toxins could also be thus eliminated, the experiment was made with tetanus toxin. After careful control experiments it was found that the toxin could be washed out of an animal after the symptoms of tetanus had been well established for some time, many times the lethal dose of toxin having been administered. For full particulars of the process we must wait until the investigators themselves publish their results.

Edward W. Schauffler.

TETANY or **TETANILLA.**—The "little tetanus" is a disease characterized by attacks during which there occur bilateral tonic spasms of various groups of muscles, most frequently of those of the upper extremities; also by extreme hyperexcitability of the peripheral motor nerves in response to mechanical and electrical stimulation. We shall see that, although the disease has a very distinct symptomatology, it is often confounded with other diseases, and is so little known that no special mention is made of it in some of our largest treatises, that it is referred to incidentally only in Reynolds' "System of Medicine," as a symptom associated with others of spinal irritation, and that in Pepper's "System" it is merely alluded to in the article on Tetanus.*

History of our Knowledge of Tetany.—In 1830 Steinheim described this disease as a special form of articular rheumatism; in the following year Dance published "Une observation sur une espèce de tétanos intermittent," and in this article expressed the view that the intermittent character of the spasms proved the disease to be of the malarial order. In 1852 the entire subject was reviewed by Lucien Corvisart, and it was he who proposed the name tetany. Previously to Corvisart, the great Trousseau, as early as 1845, had observed this disease in nursing women, and supposed a connection between tetany and the function of lactation; he therefore termed it "contracture rhumatismale des nourrices," but, having observed the same trouble later on in children and adults after intestinal obstruction, he was forced to abandon his "nourrice" theory. It was Trousseau also who first discovered the very important fact that these attacks could be excited by compression of the arteries and nerve trunks of the affected extremity.

Many of these cases were regarded, in Germany particularly, as cases of professional neuroses, professional spasms, until Kussmaul showed conclusively that there was a distinct difference between this affection and the ordinary professional neuroses. Riegel insisted on the causal relation between the disease and the presence of entozoa in the intestines. Erb and Chvostek examined the electrical behavior of the affected muscles, Chvostek directing particular attention to the increased mechanical excitability of the affected muscles and nerves. In 1874 Langhans published the first case of tetany in which a careful post-mortem examination had been made, and in 1881 the late Dr. Nathan Weiss, of Vienna, published an excellent monograph on "Tetany"† (Volkmann's Vorträge, No. 189), in which he described the disease most carefully, reviewed the entire literature of the subject, and showed an interesting connection between tetany and the surgical removal of goitre.

Etiology.—The disease is most apt to occur in young persons; in children between the ages of four and six years; then again at the age of puberty; while the majority of cases of tetany are observed in persons between the ages of sixteen and thirty-five years.‡ Pregnancy, child-bed, and lactation appear to be predisposing causes. It is now well established that it is *not* one of the professional neuroses, although cobblers evince an unusual predisposition to the disease. Persons who have been exposed to cold or wet seem particularly liable to attacks of tetany. Intestinal irritation is another cause; stubborn constipation or protracted diarrhœa has been followed by tetany. Riegel (*Deutsches Arch. f. klin. Med.*, Bd. xii.) instances a case in which attacks of tetany were inhibited by the removal of the ova of tænia mediocanellata and trichocephalus dispar; and Weiss makes mention of a case in which tetany occurred as a complication of typhoid fever. The attacks of tetany disappeared as the typhoid (intestinal) symptoms subsided, and returned with a relapse of the intestinal symptoms. Tetany has also been observed in the wake of smallpox, Bright's disease, malaria, cholera, and in children during the period of dentition. It has also been observed after severe mental shocks. The causal connection between extirpation of goitre and tetany, as proven by the cases of Weiss, has been referred to above. The frequent association of tetany with gastro-intestinal disorders has led to a belief in the auto-intoxication origin of some of the cases. Eulenburg states that non-malignant stenosis of the pylorus, with subsequent dilatation of the stomach, is a condition particularly favorable to the development of tetany. And finally, it is to be noted that tetany occurs frequently as an epidemic,* and that it is of much more frequent occurrence in some countries than in others. The present writer observed a number of cases of tetany in Vienna, while he has seen only very few typical instances, in this country, among a large number of neurological cases of every description.

Symptomatology.—In describing the symptoms of the disease we must mention the symptoms noticed during the *attack* and during the period of *latency*.

The *attack* is preceded by vague tingling pains, by formications in the hands, forearms, and legs; these sensory symptoms are followed by a feeling of stiffness in the hands and legs, and soon afterward the spasms are fully developed. These tonic spasms occur most frequently in the upper extremities, and give rise to such a marked rigidity of the muscles that passive movements are impossible. The position of the hand varies according to the groups of muscles affected by the spasms, whether flexors or extensors. It is a common occurrence for the hand to assume the shape of the accoucheur's hand as it is ready to be introduced into the vagina. Occasionally, also, the thumb is so firmly pressed upon by the flexed fingers that the nails are buried in the skin of the palm of the hand. In some rare cases there is complete extension of all fingers. As a rule, the forearms are flexed, the upper arms in adduction; it is exceptional for the arms to be in abduction and removed from the trunk of the body.

Mild cases of tetany are apt to consist only of a series of such attacks as have just been described; and this is true even of the earlier stages of severe forms of tetany. In a large majority of cases, however, and particularly in the later stages of the disease, spasms are apt to affect other groups of muscles, viz., the muscles of the lower extremities, causing adduction of the thighs, with extension of the hip- and knee-joints, and plantar flexion of the foot, the toes being bent forcibly toward the soles of the feet. The spasms may also affect the muscles of the abdomen, chest, and back. The tonic contractions of the abdominal and thoracic muscles may interfere with the movements of the diaphragm and with respiration, causing severe dyspnœa and universal cyanosis. If the muscles of the neck be involved additionally, the return of venous blood from the brain may be retarded, and Weiss reports one case in which loss of consciousness was the result. Opisthotonos is frequently the result of spasms affecting the muscles of the back. Trismus is occasionally observed, but never in the beginning as in

* An excellent chapter on tetany will be found in Gowers' "Diseases of the Nervous System."

† The present writer is greatly indebted to this monograph for many of the historical and other facts to be found in this article. He has made liberal use of Weiss' monograph, without in each instance acknowledging his indebtedness.

‡ Gowers has tabulated 142 cases, and of these he found that 42 occurred at the ages of from one to four years and 36 at the ages between ten to nineteen years.

* Cases of epidemic tetany have been reported as occurring in schools and prisons of France.

tetanus. In other (severe) cases again, spasms of the ocular muscles, of the œsophagus, of the larynx (spasmus glottidis), and of the muscular apparatus of the bladder (desire to urinate, but micturition impossible) have been observed.

During the attack patients complain of severe pain in the affected muscles; there is, furthermore, marked diminution of tactile sensibility in the extremities, the patients not being able to distinguish the character of objects placed upon the skin, and having the feeling, when standing on the bare floor, as though they were walking on velvet.

In a few cases a rise of temperature to 104° F. has been observed; Weiss observed a rise in only one case out of twelve.

Headache, vertigo, tinnitus aurium, and excessive perspiration are other symptoms which are occasionally observed during an attack of tetany. The attacks may last only a few minutes, but may at times last for hours and even days. Severe attacks of tetany may bear a striking resemblance to genuine tetanus; but it may be noted that there is no initial spasm of the masseters in tetany, and that in this form the spasms spread from the periphery centripetally, and not centrifugally as is the case in tetanus; and, furthermore, it is evident that the reflex excitability is not nearly so great in tetany as in tetanus. There is also this further distinguishing characteristic, that in cases of tetany the patient may be entirely free from attacks for hours, days, weeks, and even months.

A. Westphal (*Berl. klin. Wochenschrift*, 1901, p. 849) has called attention to the occasional association of epilepsy with tetany, and believes that toxic products are important etiological factors in both diseases.

Symptoms of the Latent Period.—In the intervals between the attacks the patient may be entirely well; but some exhibit even at this time weakness, with rigidity of the affected muscles. The calf muscles are particularly apt to be the seat of slight tonic contractions. Weiss observed in one case, during the latent period of the disease, tonic rigidity of the calf muscles, and fibrillary as well as fascicular contractions in the quadriceps cruris and vastus externus; in another case Chvostek observed slight contractions of the orbicularis palpebrarum.

The intervals between the attacks of tetany may vary in duration from several hours to a few days, and even a few months. Of course, we can speak of a latent interval in the course of the disease only in case the disease can be proven still to exist. This can be done by proving the presence of Trousseau's symptom, and of increased electrical and mechanical excitability.

Trousseau's Symptom.—This symptom refers to the fact discovered by Trousseau, that in persons afflicted with tetany a characteristic attack can be elicited by pressure upon the large nerve trunks and arteries of the extremities usually affected during an attack. The attacks cease as soon as the pressure is removed. Kussmaul and Quincke maintain that in some cases pressure on arteries only is necessary, while in other cases the slightest pressure on a nerve trunk is sufficient to produce contractions of all the muscles supplied by this nerve. *Trousseau's symptom is present in no other convulsive disease.*

Increased electrical excitability is another symptom observed during the *latent* period. Erb, Chvostek, and Weiss showed that the motor nerves of the extremities and of the trunk, in cases of tetany, exhibited an increased response to both the faradic and the galvanic currents. They could not only obtain the cathodal closure contraction (CCC) with very small currents, but were able, with moderate currents, to obtain CCT and even an AOT, which had not been observed in any other condition; while Chvostek reports having obtained a COT—a condition unheard of in man. Erb failed to obtain these phenomena in the facial, but Chvostek and Weiss claim that they were as well able to obtain these phenomena with the facial as with any nerve of the extremities. J. Hoffman found an increased excitability upon mechanical and electrical stimulation of the sensory as well as of the motor nerves. Erb found the electrical excitability greatest at a time when the attacks were most frequent, and it was he who first ventured the suggestion that the increased electrical excitability might be used as a diagnostic test during the latent period of the disease.

Increased mechanical excitability is another well-marked symptom; a simple tap with a percussion hammer upon a nerve trunk being sufficient to produce contractions of the muscles supplied by the nerve. Pressure with a lead-pencil upon the focal point of the pes anserinus is followed by contractions similar to those which a strong faradic current applied to this point would have produced. Increased reflex excitability of the nerve must be taken as an explanation of this phenomenon. At all events this should be the first employed diagnostic test during the latent period of the disease, as it certainly is better to try this test than to attempt to excite an attack by pressure upon a large nerve trunk or a large artery.

Pathological Anatomy.—In spite of the post-mortem examinations made by Langhans, Weiss, and others, there is little or nothing known of the pathology of tetany. Langhans claimed to have found a periarteritis and periphlebitis of the blood-vessels of the white commissure, and of the anterior horns in the cervical portion of the spinal cord. Weiss found nothing of the sort in his case. He has built up an ingenious theory of the disease, according to which he believes that the attacks of tetany are due to an irritable condition of the gray matter of the medulla and spinal cord, and that this irritable condition is due to sympathetic disturbances, causing irregularities in the vascular innervation of the blood-vessels of the spinal cord: but this is mere theory. H. Schlesinger is of the opinion that tetany is a disease of the entire nervous system; that some of the symptoms are due to involvement of the peripheral nerves, and that the spasms and Trousseau's symptom are due to an increased excitability (of vaso-motor origin?) of the central nervous system, brain, medulla oblongata, and spinal cord. A satisfactory explanation of the disease or of the attacks cannot be had.*

Differential Diagnosis.—There can be no difficulty as to this. There is the mere possibility of confounding an attack of tetany with genuine tetanus. It is necessary to remember the distinctly centripetal character of the attack of tetany, the fact that the disease never begins with trismus, and, above all, the shortness of the attacks, and the existence of a latent period—all of which differs widely from what is observed in real tetanus. During the latent period Trousseau's symptom, and the increased electrical and mechanical excitability, help to establish the diagnosis.

Prognosis is favorable except in those few cases in which the spasms affecting the respiratory muscles may lead to serious lung trouble.

Treatment.—In the way of treatment, it is necessary above all things to remove the active or predisposing cause, to change the patient's abode, to procure absolute rest for him, and, if there is suspicion of intestinal irritation, to look to this, to purge the bowels, and to remove entozoa that may happen to be present.

During the attack, the physician will have to resort to the hypodermic use of morphine, possibly of hyoscyamine. Applications of ice to the back of the neck helped to inhibit an attack in one of Weiss' cases. As soon as the attack is over, it will be well to administer chloral hydrate in daily dose of ʒ i.–ʒ ij.; or the combined bromides in doses of ʒ iss.–ʒ iiss. pro die. During the intervals careful electrical treatment (stabile currents ascending from peripheral nerve trunks), as well as methodical lukewarm baths, deserves a trial; but it is gratifying to know that the majority of cases will get well without any treatment at all. The use of thyroid gland and of thyreoiodine has been favored by some. There can be no objection to a careful use of these prepara-

* Gowers, relying on cases in which a wasting of the muscles has followed upon tetany, believes that the trouble starts in the motor cells of the spinal cord.

tions in suitable cases. By way of warning, we would suggest to the physician not to employ either counter-irritation or the faradic current. *B. Sachs.*

TETRA-ALLYL-AMMONIUM ALUM and **TETRA-ETHYL-AMMONIUM-HYDROXIDE** are soluble crystalline salts used in dose of 0.06–0.12 gm. (gr. i.–ij.) as uric-acid solvents. *W. A. Bastedo.*

TETRA-IODO-DI-CHLOR-SALICYLIC ACID, (C_6S_2-HCl.OH. COOH)$_2$, is a reddish-yellow antiseptic dusting powder obtained by heating salicylic acid with sulphur chloride. It is soluble in alkaline solutions.

TEXAS.—The great extent of this State, its situation on the continent in relation to the surrounding land and water, and the diversity of its surface in mountain, plain, hill, and desert naturally produce a great variety of climatic conditions. The area of the State embraces 237,504 square miles, extending over eleven degrees of latitude and thirteen of longitude. It stretches "from a parallel very nearly coincident with the extreme southern portion of Florida to one touching the southern boundary of Virginia; while east and west it is bounded by the meridians coincident with Sedalia, Mo., and Leadville, Col." [Morse K. Taylor in the previous edition of the Handbook.] In the southern portion, on the gulf coast, we have the zone of tropical cyclones, as witness that of September 7th, 1900, at Galveston, which destroyed over six thousand lives and a considerable portion of the city; while on the northern border the arctic blizzards are experienced.

The eastern and southern portions of the State are at nearly sea-level, and, as one goes northwest, the elevation increases until an altitude of seven thousand feet is reached in the Chinanti Mountains. The intermediate country consists of "high, wide rolling prairies and river bottoms." The vegetation also varies greatly, according to the altitude and topography of the surface. The eastern border, for example, is heavily timbered, while in the west the land is barren of trees, and only the cacti and the stunted mesquite are found. In the extreme south we have a subtropical flora, and in the central portion are fertile agricultural lands where various cereals, fruits, and flowers of temperate latitudes are cultivated. The climate of such an extensive area, so diversified and so situated, cannot well be considered as a whole, except in the most general manner, and it is only by taking various portions of the State, each representing peculiar climatic characteristics, that one can obtain an adequate and intelligent idea of the climate, or rather climates, of the whole State. Taylor's division (*loc. cit.*) appears to be a serviceable one for this purpose. He divides the State into five districts: Eastern Texas, the gulf district, southwestern Texas, northwestern, and central Texas.

Only those districts which offer some claim as health resorts need occupy our attention to any great extent. The eastern district is comparatively level, has no elevations much above five hundred feet, and is heavily timbered throughout. Its climate is a moist, warm one, with a mean relative humidity of seventy-four per cent., and an annual rainfall of about forty-nine inches, with exacerbations in the form of heavy rains and floods. The annual mean temperature is about 66° F. Yellow-fever epidemics occur in this section. It is not a wholesome climate.

The gulf district has a coast line of about three hundred and seventy-five miles, and its surface is comparatively level. Its climate is of a subtropical nature—hot, moist, and windy. For a large portion of the year the winds are from the sea. The annual mean temperature is 73.9° F.; the rainfall, 41 inches; and the relative humidity, 78.6 per cent. Away from the river bottoms it is said to be generally healthy, although malaria is prevalent. During the summer the gulf coast is said to offer a soft, equable temperature and excellent surf bathing, the heat being tempered by a pleasant sea breeze. The beach at Galveston is a fine one, and is a very popular resort; the accommodations are reported to be good.

Southwestern Texas is higher than either of the two previous districts, much of the northern portion being at an elevation of two thousand feet. This district is well drained, and is beyond the yellow-fever line. The climate is moderately dry, particularly so on the Rio Grande line. The annual mean temperature is 68.1° F.; the relative humidity, 67.3 per cent.; and the rainfall, 26.6 inches. "The possibility of outdoor employment," says Taylor, "during the whole year makes this portion better suited for those in delicate health who wish to remain a length of time, and, as they say, 'rough it,' than any other portion of the State. Life on the ranches, though lonely for many, is novel and interesting, and often beneficial." One should, however, bear in mind the wise advice of Hinsdale, that no invalid should go into the country districts unless he is able to endure positive hardships and to subsist on the coarsest food.

While, in general, the summers in Texas are hot (and the invalid from the North is advised not to go there at this season), yet in the southwestern portion "the heat is so tempered by the winds that its intensity is greatly modified . . . and the nights are always cool and dry. From May to October there is rarely any dew, so that persons may sleep in the draughts, on their porches, verandas, housetops, or under the trees with perfect freedom from liability to take cold" [Taylor]. The same authority also avers "that the summer nights of southwestern Texas are more delightful than those of any interior region south of the great lakes." The two health resorts of Boerne and San Antonio are situated in this district, and the reader is referred to Vol. II. and to the first part of the present volume for a consideration of their climate and merits.

Central Texas, which contains the capital, Austin, in the southern portion, ranges from six hundred to two thousand feet above sea-level, and embraces the best agricultural land in the State. It is well settled, and contains several cities. The whole district has an annual mean temperature of 65.4° F., and an annual rainfall varying from 23 to 41 inches, and a relative humidity of from 59 to 67 per cent. The most desirable portions of central Texas for a winter residence are those centering about Dennison on the northern border, Corsicana about 120 miles directly south, and Austin 150 miles south of the latter town. "The general aspect of the country is pleasing," says Taylor; "it is productive and of easy cultivation, and for one seeking a home in a mild and healthful climate it offers advantages scarcely surpassed in the United States." The average maximum temperature at Austin is 99° F., and the average minimum 19°. The annual rainfall is about 33 to 35 inches. The "northers" are experienced throughout this district, especially in the northwestern portions.

The northwestern portion of the State is dry, more or less barren, and sparsely settled, and its climate is characterized by great dryness, small annual rainfall, low humidity, and almost continual sunshine. In the extreme northwestern portion of this district, not far from the boundary line between New and old Mexico, is the health resort of El Paso, a city of 15,000 inhabitants, with an elevation of 3,764 feet. The surrounding country is arid and barren, except as irrigation has been instituted; the city itself, however, is quite attractive. There are several hotels, one or more good boarding-houses, a modern hospital, and a sanatorium. There are various churches, good public schools, and a military fort—Fort Bliss—near by. A large majority of the exports from Mexico enter the United States by way of El Paso. From the middle of September to the middle of May the climate is suitable for tuberculous invalids; after that time it is too hot for comfort, at least in the middle of the day. As Hinsdale* remarks, El Paso is a good place in which to begin the process of acclimatization to regions of greater rarefactions of air. The soil is dry and porous, except near the river (Rio Grande), where it is adobe. Water can be obtained from artesian wells. The peculiar climatic features which render this a desirable resort are the extreme dryness and purity of the air, the almost constant sunshine, and the mild winter temperature. The moderate elevation, moreover, adds a freshness and tonicity to the air. There is no malaria or fog, and in the winter the winds are not high, though there are occasional dust storms. The rainfall is very low, averaging from 9 to 13 inches during the year, falling principally in the summer, and some years there is hardly any rain at all. The mean relative humidity is 37 per cent. for the year, and for the season from September to May 49 per cent., according to Hinsdale. The average monthly mean temperature is: For January, 43.8° F.; February, 47.9°; March, 55.5°; April, 64.5°; July, 81.2°; and for the year, 63.3°. There are evidently not many resources for the diversion of the visitor. El Paso is reached by the Atchison, Topeka and Santa Fé Railroad.

In conclusion, a few words as to the "northers." They are cold, dry winds sweeping down, as their name indicates, from the north or northwest, occurring during the winter at intervals of about seven days, and lasting twenty four to forty-eight hours. They are most prevalent and severe in the northern portion of the State. They come suddenly, and produce a sudden marked lowering of the temperature, not infrequently reducing it from summer heat to ten or fifteen degrees below the freezing point in a few hours. Their effect has been thus described: "Northers are intensely dry, and soon drink up all the moisture on the surface of the earth and of the objects upon it capable of yielding their humidity. Great thirst of man and animals is experienced, with many an itching of the skin, a highly electrical condition of the skin of horses and cats, a wilting and withering of vegetation, even when the temperature would not account for it." Taylor (*loc. cit.*) considers their influence invaluable as a sanitary flushing of the country, and that the air following in their track constitutes one of the chief curative agencies in this climate, acting as a vigorous tonic. *Edward O. Otis.*

TEXAS FEVER. See *Arachnida.*

TEXAS SOUR SPRINGS (known also as Caldwell Springs).—Caldwell County, Texas.

Post-Office.—Luling. Hotel.

Access.—Via Galveston, Harrisburg and San Antonio Railroad to Luling; thence six miles north to the springs. The location may also be reached by way of the Burdett Mineral Wells (*q. v.*), which are not far distant.

This is quite a new resort, although the existence of the springs has been known since the early settlement of the country. Tradition has it that the aborigines employed the waters for medicinal purposes, and that Colonel Davy Crockett bathed his wounds in their cool and limpid flow after his famous single handed fight with the Mexican lions in this vicinity. The springs are located in a rolling country, at an elevation of seven thousand feet above the sea. The air here is dry and balmy, the winters being mild and the summers breezy and pleasant. It is stated that malaria never develops in the neighborhood. The springs are five in number, and afford about sixty gallons of water per hour. They differ but little in their chemical constitution. The following analysis was made by Prof. H. H. Dinwiddie, of the Texas Agricultural and Mechanical College: One United States gallon contains (solids): Aluminum and potassium sulphate, gr. 100.08; ferrous sulphate, gr. 7.58; magnesium sulphate, gr. 16.17; sodium chloride, gr. 42.74; calcium sulphate, gr. 125.01; magnesium chloride, gr. 132.84; lithium chloride, a trace; free sulphuric acid, gr. 7.26; soluble silicates, gr. 12.18; organic matter and loss, gr. 5.12. Total, 448.98 grains.

This analysis shows a rich and potent mineral water. It is a well-marked example of the acid-saline-chalybeate class, and exerts a marked influence when taken internally. It possesses cathartic, alterative, diuretic, and tonic properties. Locally it is astringent, and is beneficial as a lotion in conjunctivitis, a gargle in pharyngitis, a douche in leucorrhœa, etc. The water is used commercially, and an extract prepared from the dried residue is also found in the markets under the name of the "Texas Sour Mass." It is said to possess all the virtues of the water. *James K. Crook.*

THALAMUS OPTICUS. See *Brain.*

THALLINE.—The name *thalline* was given by Skraup, of Vienna, to a body prepared by him synthetically in 1884, of which body the *sulphate* and *tartrate* salts have been used in medicine. Chemically, thalline is *tetrahydroparaquinanisol*, $C_9H_6H_4N(OCH_3)$. Thalline sulphate, the more commonly used salt, is in the form of a cream-colored powder, of a pleasant odor, resembling a perfume of some flower, and of a taste which, though at the outset biting and bitterish, leaves an aromatic flavor upon the palate. The salt dissolves freely enough in water, sparingly only in alcohol, and is insoluble in ether.

Thalline is a fairly efficient antipyretic medicine, operating after the general manner of antipyrin and kairin, and holding rank about midway between those two agents. With efficient dosage, a fall of from 2° to 4° F. can be procured within an hour or so after administration; but very soon after the extreme of reduction the temperature begins to rise again, and quite rapidly, commonly regaining its original elevation in from two to four hours. This after-rise is quite frequently accompanied by a chill, lasting from a few minutes to an hour. Other symptoms commonly observed are a slight diminution in pulse rate and respiration rate, and a very considerable diaphoresis. Vomiting occasionally occurs, but collapse has not been reported, though the subjects may show some depression of strength and present a more or less cyanotic appearance when under the full influence of the drug. Thalline may be detected in the urine within an hour and a half after administration, and its presence may give that secretion a characteristic darkish-green color. Experimentation upon animals has shown that the medicine, in sufficient dosage, is competent to cause arrest of the heart in diastole, to hasten coagulation of the blood, and to exercise a destructive influence on the hæmoglobin of the red blood corpuscles. Some consider that the antipyresis wrought by thalline is due to this action of the drug on hæmoglobin (Brouardel and Loye).

Thalline has been used in medicine as an antipyretic, the dose of the sulphate ranging from 0.25 gm. (gr. iv.), given hourly, up to 1 gm. (gr. xv.), to be repeated in from two to three hours. So large a quantity as 7.33 gm. (gr. cx.) has been given in twenty-four hours without inconvenience (Maragliano). Thalline sulphate may be administered in form of pill, wafer, or in aqueous solution, aromatized to taste. But the thalline salts have practically gone out of use in medicine, having been superseded by more modern antipyretics, which are equally efficient and much more kindly in operation. No preparation of thalline is official in the United States Pharmacopœia. *Edward Curtis.*

THALLIUM.—Thallium is a somewhat rare metal. It was discovered by Crookes in 1861. It has been classed chemically with the metals of the lead group, but its reactions are in many cases different and peculiar to itself. It forms salts which in many respects resemble the corresponding ones formed by potassium and the other alkalies.

Symptoms in Animals.—Its action was investigated by Lamy in 1863, who found that the symptoms in a dog

* "System of Physiological Therapeutics," vol. iv., Book II., "Climatology."

were general weakness, restlessness, tremor, loss of appetite, dyspnœa, salivation, and severe intestinal pains. Convulsions of the posterior limbs occurred, and later these became gradually paralyzed. Paulet, in rabbits, after injection of thallium, found general tremor, loss of co-ordination, slowing of respiration, and death under asphyxia. He found that 1 gm. of the carbonate killed a rabbit in a few hours. Results essentially similar were obtained by Marmé. In small doses, nausea, vomiting, loss of appetite, and salivation were produced with intestinal pain and diarrhœa with bloody dejections; also slowing of both respiration and circulation with dyspnœa. Tremor and inco-ordination, both static and motor, occurred. The autopsies showed swelling and hyperæmia of the mucous membranes of the stomach and intestines with extravasations of blood therein; small hemorrhages and pneumonic infiltration of the lungs; hemorrhages in the epicardium and effusion in the pericardium. The brain and spine showed no constant changes.

The soluble salts are said to be cumulative poisons of slow elimination which may last for three weeks.

Rabuteau, using 5 cgm. of the iodide, found much the same symptoms in dogs (1883). He mentions also albuminuria.

In 1891 Luck used a double salt of thallium and sodium on cats, dogs, and rabbits. The symptoms appeared not immediately, but on the first, the second, or the beginning of the third day. They were weakness, apathy, loss of appetite, vomiting, diarrhœa with blood. Tremor of the extremities and static and motor inco-ordination were present, and twice there were clonic convulsions. The heart action was weak and rapid; the respiration slowed. Clinically there existed the symptoms of a parenchymatous nephritis. Hemorrhages were found in the stomach and intestines.

Richet found in chronic poisoning a generalized muscular atrophy, not simply a wasting of the muscles but their almost total disappearance. This affected especially the masseters, temporals, and muscles of the lumbar spine. He declares that in its great toxicity it resembles lead, while lithium is much less toxic.

Action on Man.—In 1884 Pozzi and Courtade recommended the use of iodide of thallium in doses of 0.010 gm. daily in certain cases of syphilis and obtained favorable results. They found, however, that it produced unpleasant digestive symptoms—pain in the stomach and vomiting; in some cases also they reported that the gums were reddened and there was a blue line at their junction with the teeth. These latter symptoms have not yet been confirmed by other observers. Combemale in 1898 used acetate of thallium for the profuse sweats of pulmonary tuberculosis, and found that even in the last stages of the disease it exerted a strong effect. The ordinary dose was 10 cgm., the maximum 20 cgm. He observed no toxic symptoms during the administration of the drug. Huchard relates two cases in which severe pains occurred in the lower extremities. These patients were in the later stages of phthisis. As the pains disappeared when the administration of the drug was stopped, it was concluded that they were due to the thallium.

Symptoms of poisoning in man are not common. Crookes states that he has swallowed 0.065–0.130 gm. of thallium salt without any effect. Combemale seems to have been the first to notice the peculiar and specific action of the drug in causing alopecia, or falling of the hair. This symptom did not occur while the drug was being taken, but came on later. The loss of hair was said to be total and extraordinarily rapid. This action of thallium was soon confirmed by other observers. Jeanselme reported the case of a woman who, in three days, took nine cachets of acetate of thallium, containing 3 cgm. each. Fifteen days later her hair suddenly began to fall and she lost about one-third of it. Buschke and Bettmann have succeeded in producing alopecia in animals by the administration of thallium acetate.

The writer has lately reported a case of poisoning by sulphate of thallium in a male twenty-seven years old. The symptoms were those of a multiple neuritis coming on with considerable rapidity and continuing for several weeks. There were loss of motion of the lower extremities, diminution of the sensation of a portion of the legs and feet, with pain and extreme tenderness at times in the same regions. The knee jerks were increased. The patient recovered from these symptoms so as to be fairly well in about six weeks, and in three months was able to resume work. About six weeks or two months after the beginning of the illness his hair fell out completely.

The typical or specific symptom of subacute or chronic thallium poisoning in men is the extraordinary falling out of the hair. This has proved an absolute contraindication to its use for therapeutic purposes in many cases, especially in women. The case last reported illustrates the danger of experimenting with this drug. The amount in this case was half a grain to a grain of the sulphate, which was taken every other day for three or four doses. This was done twice at an interval of about two months. There were no symptoms the first time, but within two or three days after the last dose of the second series numbness was noticed in the toes and finger-tips, and after this the neuritis developed rapidly.

William N. Bullard.

THANATOL. See *Guaiacol-ethyl.*

THEOBROMA. See *Cacao, Oil of*

THEOBROMINE-LITHIUM SALICYLATE. See *Uropherin.*

THEOCIN, $CH_2(CH_3)_2N_4O_2$, is a name given to the synthetically prepared theophylline, an alkaloid found in very minute quantity in tea leaves. It is prepared from urea by a complicated process in twelve reactions, and is the first alkaloid to be manufactured synthetically from such a simple substance. Chemically it is di-methyl-xanthin, a member of the purin group, and is isomeric with theobromine. It occurs in colorless needles and is soluble in one hundred and eighty parts of cold water, more soluble in hot water, soluble with difficulty in alcohol, and insoluble in ether. Its ammonium and potassium compounds dissolve readily in water, the sodium salt but slightly.

Minkowski finds that the diuretic action of theocin is greater and more rapid than that of theobromine, and that while it has little if any effect on the circulation, it increases the excretion of both solid and liquid. Given on an empty stomach, however, it produced nausea and vomiting unless in very dilute solution. Ach considers it nearly twice as powerful as diuretin. Meinertz, in Grawitz's clinic, studied the action in twenty-three cases and found it a very valuable diuretic in cardiac and renal affections; in four other cases in which the urinary condition was normal, there was no diuretic effect at all. The dose is 0.3–0.5 gm. (gr. v.–viij.).

W. A. Bastedo.

THERMAL ACID SPRINGS.—Inya County, California. These remarkable springs are found in the Caso Range, twelve miles east of Little Owens Lake, and sixteen miles southeast of Olamoha. The country for miles around the springs is rich in pure crystallized sulphur, having, no doubt, been ejected by the sulphurous steam in the form of sulphurous anhydride (SO_2). On being exposed to the air the sulphur was deposited pure and water liberated. This seems to be a rational explanation of the formation of these large sulphur banks. The water now flows in rather limited quantities through the small crevices and fissures, and is accompanied by sulphurous steam and vapors. The following analysis of the waters has been made by a chemist whose name has been lost: One United States gallon contains: Sodium sulphate, gr. 145.75; potassium sulphate, gr. 880.33; magnesium sulphate, gr. 891.91; calcium sulphate, gr. 69.96; aluminum sulphate (?), gr. 7,407.41; ferric sulphate (?), gr. 1,934.56; sulphuric acid (?), gr. 4,670.72; nitric acid, chlorine, ammonia, lithium, traces. Total solids, 15,997.64 grains. In Anderson's work on the mineral springs of California the above analysis is stated in parts per thousand. Its correctness cannot be vouched for. This acid sulphate water does not seem to have come into much use as yet. Well diluted and properly administered, it ought to be valuable in many conditions requiring tonic and astringent remedies. It will be observed that the water closely resembles that of the Matchless Mineral Wells of Butler County, Alabama, being, however, according to the above analysis, much stronger. *James K. Crook.*

THERMIN, tetra-hydro-beta-naphthylamine hydrochloride, $C_{10}H_{11}.NH_2HCl$, is a crystalline body recommended by Filehne as a powerful mydriatic. *W. A. Bastedo.*

THERMODIN, acetyl-para-ethoxy-phenyl-urethane, $C_6H_4.OC_2H_5.N.CH_3CO.COOC_2H_5$, is an almost odorless and tasteless, insoluble, white powder with mild antipyretic and antineuralgic properties. Dose 0.3–1 gm. (gr. v.–xv.). *W. A. Bastedo.*

THERMOMETERS, CLINICAL (θέρμη, heat; μέτρον, a measure).

Definition.—Instruments for determining the temperature of the body in disease.

History.—The ancients had no better means of estimating the temperature of bodies than that of observing the sensation of heat or of cold which they imparted to the hand. Hippocrates applied this method to the clinical investigation of diseases, and was fully sensible of the value of the information thus obtained.

The first successful attempt to represent differences of temperature to the more accurate sense of sight has been attributed both to Drebbel, of Holland, and to Sanctorius, of Italy, living in the early part of the seventeenth century. The first instruments for this purpose, called weather glasses, depended upon the expansion of air, and were both rude and inaccurate. Atmospheric thermometers of a much better pattern were afterward devised by Boyle and the academicians of Florence. The liquid was colored spirits of wine. After the spirits had been boiled to expel the air, the tube was hermetically sealed. A system of markings, or a scale, had next to be devised. The fixed points at first selected were the cold of snow or ice, and the greatest warmth known at Florence. A great deal of discussion arose, however, throughout Europe in regard to the most suitable fixed points upon which to base the scale, as well as upon the most suitable substance for use in the instrument. Newton discovered that snow and ice melt at invariably the same temperature, and that the heat of boiling water is almost as constant. These points were then selected, and are still maintained, except that the temperature of the vapor arising from boiling water is taken as being more constant than that of the water itself. Deluc and Römer demonstrated the even expansibility of mercury under the influence of heat, and adopted it in the construction of their thermometers; but to Fahrenheit is generally given the credit of having brought the mercurial thermometer into favor.

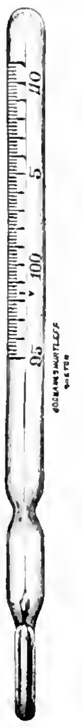

Fig. 4699.—Self-registering Clinical Thermometer.

Sanctorius is said to have adapted the thermometer to the investigation of human temperature, but fully a century elapsed before any systematic use of the instrument for that purpose was recorded. Boerhaave, Van Swieten, and De Haen are the three names which appear most prominently in the literature of thermometry in the eighteenth century. But it required another hundred years to bring thermometry into favorable clinical use.

Description.—The mercurial thermometer has been almost exclusively used for clinical purposes. It consists of an exhausted capillary glass tube, one end of which is expanded into a globular or cylindrical bulb containing mercury (Fig. 4699). Its action depends upon the great difference in the extent to which glass and mercury expand when exposed to the same degree of heat.

The scale of the thermometer is generally engraved on the stem and illuminated by a white or black stripe incorporated in the glass behind the mercurial column. A range of 10° C. (18° or 20° F.) is quite sufficient for the scale of a clinical thermometer. This should embrace from 35° to 45° C. (95° to 113° F.), limits which include the range of probable physiological and pathological temperatures. The thermometer must be long enough to bear a legible scale (not less than three inches); for the sake of portability, however, it should not exceed five inches. The bulb or reservoir should be formed of as thin glass as is compatible with strength. Thermometers having rather long but narrow reservoirs (*e.g.*, the "minute thermometer," Fig. 4700) register more promptly than those whose bulbs are short and thick.

Thermometers having a double, "twin," bulb, or a branched, "crescent" bulb are also meeting with favor, although their superiority to the simpler patterns is questionable.

Fig. 4700.—The Minute Thermometer. The column of mercury appears magnified by means of the so-called lens front.

Thermometers are now made self-registering. This was first attained in the instruments used by Currie, in the early part of the nineteenth century, by means of a small piece of iron resting upon the surface of the mercury. The register now used is known as the "indestructible" index, secured by a constriction of the tube near the bulb so narrow as to prevent the passage of an unbroken column of mercury through it. The expansion of the fluid causes it to pass the constriction in little "jumps" which render the reading slightly inaccurate, but not to the extent of one-tenth of a degree in a properly constructed instrument. The index must be "shaken down." This is best accomplished by grasping the upper end of the instrument between the thumb and fingers and giving it a short, sharp swing from the wrist or elbow.

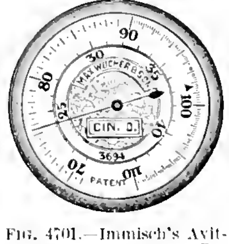

Fig. 4701.—Immisch's Avitreous Thermometer. (Exact size.)

The reading of the register is greatly facilitated by the so-called "lens-front," a conical form given to the face of the instrument, through which the column of mercury appears greatly magnified.

The avitreous (Immisch's) thermometer (Fig. 4701) depends upon the same principle as the mercurial, but its construction is different. In appearance it resembles a miniature watch. Its mechanism consists of a small metallic tube bent into a circular form, having one end fixed to a support, the other free to move, but connected by a fine spring to a shaft which carries a needle or dial indicator. The tube is filled with a highly expansive fluid. In consequence of its expansion the tube uncoils, producing a corresponding vibration of the indicator. Upon cooling the tube curls and the indicator returns to its point of repose. The dial over which the indicator moves is graduated according to both the centigrade and the Fahrenheit scales. A device for "registering" the temperatures has been added, in the form of a stop-catch passing through the stem. In action this thermometer is slower than the mercurial. It is now used chiefly as a surface thermometer.

The surface thermometer is designed chiefly for determining differences in temperature of the surface of various regions. The reservoir is usually given a flattened extremity (Fig. 4702), or is made into a coil, the object in either case being to expose as great an amount of the expansive medium as possible to the temperature of the surface to be investigated. In using the instrument the bulb must be carefully covered, in order that the result may not be altered by the temperature of the atmosphere.

The differential or metastatic thermometer was devised by Walferdin for the purpose of determining with great accuracy the fluctuations of temperature within certain narrow limits. It consists of a capillary tube of very small calibre, at either extremity of which is a small reservoir. At the junction of the upper of these reservoirs with the tube there is a slight constriction. The quantity of mercury contained in the reservoir and tube must bear such relation to the capacity of both that an elevation of temperature amounting to three or four degrees Celsius (from five to seven degrees Fahrenheit), will cause the entire lumen of the tube and reservoirs to be filled. In order to prepare the instrument for use, it must be warmed to about the highest temperature that is anticipated in the investigation to be made. The column of mercury is then broken at the point of constriction by a quick tap. The mercury in the tube rapidly falls, but is not followed by that in the upper reservoir. The lower bulb is now inserted into one of the thermometric cavities, and permitted to remain, while the fluctuations of temperature are carefully observed and recorded. The only advantage possessed by the instrument is its great delicacy, depending upon the wide space allotted to each degree. Walferdin was able with it to detect variations of temperature amounting to but one two-hundredth of a degree Celsius.

FIG. 4702.—The Surface Thermometer of Seguin.

The thermo-electric apparatus has been used in clinical investigations. It was introduced into physiological experimentation by Becquerel, especially for determining the differences of temperature which exist in different regions of the body. The apparatus was perfected by Dutrochet. Its action depends upon the physical law that when, in any metallic circuit composed of two or more different metals, the points of contact are exposed to a temperature different from that of the other parts of the circuit, an electric current is produced which is readily recognized by the magnetic needle, and may be measured by a galvanometer. The thermo-electric pile constructed in conformity to this principle has been applied to the measurement of temperatures in physiological experiments on animals by Gavarret, Heidenhain, and others, and to the determination of human temperature by Lombard and Hankel. Its action is both delicate and prompt. It can be applied to the investigation of internal temperatures by means of a properly constructed needle, composed of two or more elements brought into contact at its point. The instrument is not suitable to general clinical use, on account of its size.

The Thermograph.—Instruments have been devised by Marey and W. D. Bowkett for the purpose of automatically registering changes of temperature, by which continuous observations can be made over a considerable period of time. To these the name thermograph has been applied. They have not, however, been much used for other than experimental purposes.

GRADUATION OF THERMOMETERS.—Thermometers are graduated according to the scales of Celsius, Fahrenheit, and Réaumur. The Celsius, or centigrade, scale is used exclusively on the continent of Europe; the Fahrenheit, almost as exclusively in the United States and Great Britain; whereas that of Réaumur, at one time preferred in France and in some parts of Germany, is now retained only in Russia and Sweden. The relative position of fixed points in these scales is shown in the following table from Wunderlich:

Celsius	..	0	25	50	100
Fahrenheit	0	32	77	122	212
Réaumur	..	0	20	40	80

The subdivision of the scale between the fixed points is arbitrary; hence we find that Celsius divided it into 100 parts, or degrees, Réaumur into 80, and Fahrenheit into 212. The zero, centigrade, corresponds to the thirty-second degree of Fahrenheit; 100° C. = 212° F., and 1° C. = 1.8° F., or $\frac{9}{5}$° F. If, therefore, it is required to convert a given temperature expressed in terms of the C. scale (*e.g.*, 40° C.), the number is first multiplied by 1.8. The product in the example is 72. To this 32 is added, in order that the degrees may be counted from the same fixed point. This gives us 104. Therefore, 104° F. = 40° C.

If, therefore, C represent a given temperature expressed in the centigrade scale, the unknown equivalent of which in the Fahrenheit scale is F, the formula for finding the latter term is:

$$C \times 1.8 + 32 = F;\ \text{or},\ \frac{9}{5}\,C + 32 = F.$$

Conversely, a temperature expressed in the scale of Fahrenheit may be converted into that of Celsius by means of the formula:

$$\frac{F - 32}{1.8} = C;\ \text{or},\ \frac{5}{9}\,(F - 32) = C.$$

In the same manner the terms of the Réaumur scale may be converted into those of Fahrenheit by the formula:

$$R \times 2.25 + 32 = F;\ \text{or},\ \frac{9}{4}\,R + 32 = F.$$

Consequently, to convert Fahrenheit into Réaumur:

$$\frac{F - 32}{2.25} = R;\ \text{or},\ \frac{4}{9}\,(F - 32) = R.$$

To convert degrees of the Réaumur scale into their equivalent in the centigrade scale, it is only necessary to multiply them by 1.25.

The following table gives the thermometric equivalents within the range of physiological and pathological temperatures:

Cent.		Fahr.	Cent.		Fahr.
35	=	95	40	=	104
35.55	=	96	40.5	=	104.9
36	=	96.8	40.55	=	105
36.11	=	97	41	=	105.8
36.66	=	98	41.11	=	106
37	=	98.6	41.66	=	107
37.22	=	99	42	=	107.6
37.77	=	100	42.22	=	108
38	=	100.4	42.77	=	109
38.33	=	101	43	=	109.4
38.61	=	101.5	43.33	=	110

The centigrade scale, based upon the decimal system of numeration, is now almost universally used in scientific observations, and its adoption by the medical profession is recommended on the highest authority. The Fahrenheit scale, based as it is upon an error, has nothing to recommend it but usage.

More important to the clinician than the kind of scale which is adopted is the use of a thermometer of known accuracy. It is not essential that the thermometer shall be precisely correct in its readings throughout the entire scale so long as the exact amount of error and its location are known, for the correction may then be made in reading the register. To insure this, a certificate may be obtained through the manufacturer, guaranteeing the accuracy of the instrument, or stating to what extent it is inaccurate.

Unfortunately, mercurial thermometers do not retain their accuracy. Owing to the liability of glass to undergo molecular contraction, the bulb not infrequently becomes reduced in size and thus causes the instrument to register erroneously high temperatures. This is generally avoided by thoroughly "seasoning" the tubes before engraving the scale.

Application of the Thermometer.—The object to be attained in the use of the clinical thermometer is usually to determine as nearly as possible the temperature of the interior of the body, the blood heat. Several localities are available for this purpose, on account of the nearly constant character of their temperature, but the axilla, the mouth, and the rectum are most employed. At times the conditions of disease render necessary the selection of other localities, as the groin, the urethra (female), the vagina, or the closed hand, and it has been proposed to take the temperature of freshly voided urine. The mouth is the most easily accessible. The bulb should be placed under the tongue, and the lips closed on the stem. The mouth must remain closed during the observation. If oral respiration has been carried on previous to the introduction of the instrument, a minute or more should be allowed for the rise of the mercury beyond the time that would otherwise be required.

In many cases the axilla will best answer the purposes of thermometric investigation. The arm-pit must be thoroughly dried, if moist, before the introduction of the thermometer. The instrument should then be inserted into the middle of the axilla in such a manner as to insure contact with the skin only. The cavity is then closed by pressing the arm firmly against the chest, the forearm being drawn slightly forward. It is advisable, when practicable, to use the thermometer in the axilla of the side upon which the patient has been lying. From three to five minutes are usually required for a correct register of the axillary temperature.

Taking the temperature in the rectum yields the most trustworthy results, particularly in children. The use of the urethra or vagina is resorted to only in such conditions as Asiatic cholera, when the temperature of the axilla has been found as much as 7° C. (12.6° F.) below that of the vagina; and the temperatures of the mouth and rectum are also unreliable. Whatever locality is selected in an individual case, the same should be used for all subsequent observations.

Thermometric observations should be made at stated intervals, the frequency of which must depend upon the character of the case and the object of the examination. In the commencement of a febrile disease it is often necessary, in order to arrive at a correct diagnosis, to take the temperature at frequent intervals, every half hour, every hour, or every two hours; but regular morning and evening observations are, as a rule, sufficient for the requirements of treatment. These are best taken between 7 and 9 A.M., and between 5 and 7 P.M. If, however, the points of maximum and minimum temperature are found not to occur in these intervals, the times must be made to conform to the peculiarities of the case.

In addition to the periodical observations, the thermometer should be used upon the occurrence of any phenomenal event during the progress of the disease, as after a rigor, a sweat, or psychical disturbances.

The systematic observation of temperature changes is essential to the intelligent treatment of almost every febrile disease. The attendant should be provided with a reliable self-registering thermometer, with instruction how and when to use it in the absence of the physician.

It is not enough that the temperature be regularly measured; it must be regularly recorded on a chart prepared for that purpose. Every chart should bear the name of the patient, the diagnosis of his disease, the region in which the temperature is taken, the date and time of day. Its value is enhanced if it have recorded upon it the rate of the pulse and respiration at each thermometric observation, the occurrence of critical evacuations, the alvine dejections and urine, the explanation of any anomaly of temperature or other feature of the disease.

The Temperature in Health.—In speaking of the body temperature, whether physiological or pathological, reference is usually had to the temperature of but a single thermometric region, which region, accuracy of statement requires, should always be indicated in clinical reports.

The temperature of the axilla in health averages about 36.89° C. (98.4° F.), as stated by Liebermeister, or 37° C. (98.6° F.), according to Wunderlich. It varies, however, between 36.40° C. and 37.77° C. (97.5° and 100° F.). Landois states, as the average of five hundred observations, 36.49° C. (97.68° F.). The temperature of the mouth is from a fifth of a degree to a degree higher than that of the axilla. The last-named authority gives as the average 37.19° C. (98.94° F.). The rectal and vaginal temperatures vary from 37° C. to 38° C. (98.6° F. to 100.4° F.). Thermometric observations in the closed hand are too variable for clinical purposes, as they are liable to be altered by external conditions of heat and cold. Römer places the variation which is liable to occur in this region at 6° C. (10.8° F.).

The factors which are generally recognized as influencing the results of thermometric observations may be summarized thus: 1. The region in which the observation is made; the closed cavities are warmer than exposed parts, the trunk is warmer than the limbs. 2. The temperature is higher in the extremes of life than in middle age. 3. The taking of a full meal causes a slight temporary depression of the temperature; digestion elevates it. Fasting lowers it. Alcohol produces a prompt but transitory depression, after which the temperature again rises to about the normal. 4. Physical exercise short of fatigue causes a slight rise of temperature, whereas mental exertion is said to depress it. 5. The body is coolest in the morning, gradually becoming warmer until evening, reaching the maximum, as a rule, between five and seven o'clock. A gradual decline to the morning minimum occurs during the night. This daily fluctuation ordinarily amounts to a little more than 0.5° C. (1° F.). 6. Prolonged exposure to heat causes a slight elevation of temperature, exposure to cold a slight depression. A marked effect is produced by agencies which promote or retard the radiation and convection of heat from the body. 7. The nervous system exerts a considerable influence over the bodily temperature, as has been shown by the experiments of H. C. Wood and others.

The Temperature in Disease.—A large proportion of diseases are accompanied by an elevation of temperature. In a comparatively few, there is at some period a decline below the normal. In order to denote a morbid process, in the absence of other positive signs of disease, the temperature must remain for several hours outside the bounds of health. The temperature in febrile affections undergoes a fluctuation from morning to evening and from day to day, which is typical of the underlying morbid process. By the use of the thermometer we are able to recognize this fluctuation and estimate from it the severity of the disease, and any variation which may occur in the course of the affection as a result of complications, accidents, or treatment.

The thermometer is therefore a valuable aid in diagnosis, in prognosis, and in treatment.

In Diagnosis.—The early diagnosis of infectious diseases is of the utmost importance. By the use of the thermometer we are often able, more than by any other means, to corroborate our suspicions of their existence, or, on the other hand, to disprove the evidence of fictitious symptoms. Complications arising in the course of a fever and relapses from convalescence are usually indicated by a more or less pronounced alteration of the temperature range, or by a return of high temperature.

Thermometry is no less valuable in the diagnosis of certain chronic affections, but more particularly for determining their activity or latency at the time of the observation. This is particularly true of tuberculosis. The thermometer has led to the discovery of this affection in individuals who had exhibited no subjective manifestations of the disease.

An inequality of temperature between corresponding surfaces of the body, in the absence of local inflammation, often points to the existence of paralysis of the cooler part, or of other nervous disorder, a fact which is especially of value in the presence of coma.

A diagnosis cannot be based upon a single thermometric observation. A series of observations must be made before we can learn enough of the temperature range to render a differential diagnosis possible. The absence of abnormal temperature conveys more positive information than does its presence.

Notwithstanding the value of thermometry, its results are not infallible. A sudden rise of the temperature may be due to a specific infection, but it may arise solely from an acute attack of indigestion. The taking of food, exercise, and excitement are liable to elevate the temperature in disease, as does also the retention of urine or of fæces. Due caution is always to be exercised in estimating the diagnostic as well as the prognostic importance of an elevated temperature in women, when accompanied by hysterical manifestations, when the pyrexia often appears to be due solely to the peculiar condition of the nervous system. Children are subject to sudden elevations of temperature as a consequence of the most trivial disorders, such as a simple angina or a disturbance of digestion.

In Prognosis.—The thermometer is an aid to prognosis in the extent to which it enables us to detect an approach of the temperature to the danger line. But the points at which the temperature crosses the lines of danger are not fixed points, and depend in most instances upon a combination of circumstances peculiar to the individual case. A few more or less positive rules may, however, be stated.

When the temperature reaches a height of 40° C. (104° F.), it is considered a factor of considerable gravity in prognosis. When 40.5° C. (105° F.) is passed the febrile state is termed "hyperpyrexia," and the gravity of the prognosis rapidly increases until 42.5° C. (108.5° F.) is reached, when death is usually imminent. A few cases of recovery from a temperature of 43.3° C. (110° F.) have occurred. In a few instances recovery has been reported after hyperpyrexia ranging from 44.5° C. to 50° C. (112° to 122° F.). Anomalies of such rarity, even if real, have little or no scientific value.

It is not when considered by itself that the temperature is of most value in prognosis, but when taken in connection with the other features of the disease in which it occurs; for in some diseases hyperpyrexia is frequent, whereas in others it is exceptional. A temperature which in one malady would be looked upon as of the gravest import, would in another be considered of less significance. Acute articular rheumatism, scarlatina, relapsing fever, and tetanus, for example, are often attended with hyperpyrexia, 41° to 42° C. (105.8° to 107.6° F.), which is not necessarily serious. Yet persistently high temperature is an evil omen in these diseases. A high evening temperature is less to be feared if the morning remission be considerable than if it be slight. An evening hyperpyrexia followed by an equal or still higher morning temperature is very apt to foreshadow death by a short interval, the temperature, as a rule, continuing to ascend until the fatal issue. It follows, as a corollary to this, that a high morning temperature is more to be feared than a high evening elevation.

A sudden pronounced rise of temperature after it has, in the ordinary course of the disease, declined to near the normal, is generally of evil import, because it often denotes the development of a complication, except in such diseases as malaria, smallpox, and relapsing fever.

A persistence of pyrexia, even of low degree, after the other symptoms have subsided, very often indicates a delayed convalescence, generally from the presence of a complicating affection, as when a catarrhal pneumonia or tuberculosis follows measles or smallpox; or when sepsis follows typhoid fever.

Many febrile diseases undergo a more or less rapid defervescence, involving a fall of temperature to or below normal; but under other circumstances a sudden marked decline is often as much to be feared as a sudden rise, particularly if the fall be accompanied by acute prostration. The designation "collapse temperature" has been applied to a fall below 35.5° C. (96° F.); falling below 34° C. (about 93° F.), it has been called algid collapse. A rapid fall of temperature may augur evil to the patient, without, however, reaching a subnormal degree.

In some conditions the temperature falls from the norm without previous elevation, as in certain forms of insanity, in emphysema, asthma, cardiac lesions, and in the coma of alcohol and narcotic poisons. In these the prognosis is not always so grave as the temperature would, under other circumstances, indicate. Several well-authenticated recoveries have occurred after a temperature as low as 37.7° C. (90° F.), the result of alcoholism.

In Treatment.—Here a thorough knowledge of symptomatology, including the usual temperature range of the affection in which the observation is made, is imperative. It is generally recognized that a high temperature demands prompt recourse to the application of cold or other remedies to reduce it. *Per contra*, a subnormal temperature calls for the application of heat and the use of such measures as promote heat production or retard its radiation. The cause of the pyrexia must in all cases be taken into account. *James M. French.*

THIGH, THE.—The term thigh is used to mean the part comprised between the hip and the knee. In this sense it is limited above by the line of the groin (Poupart's ligament) in front, and the gluteo-femoral crease behind. The patella and knee-joint mark its boundaries below.* In its restricted sense, as the regio femoralis of regional anatomy, the thigh has more artificial, but more definite, boundaries. It is limited above and posteriorly by the gluteo-femoral crease and anteriorly by a line drawn 12 to 15 cm. under Poupart's ligament (Lig. inguinale) and below by a line drawn around the limb from 3 to 8 cm. above the superior boundary of the patella.†

In this restricted sense the inguinal region (regio subinguinalis) lies between its superior boundary and Poupart's ligament. However, the separation into two regions at this point is entirely artificial.

Various bony prominences aid us in determining the relations of the structures of the thigh. The most important are the anterior superior spine of the ilium, the crest of the pubis, the tuber ischium, and the great trochanter above. Below, the patella, the internal and external condylar processes serve as guides. The most important muscular landmark of the thigh is formed by the sartorius. This is best seen when the limb is raised, and it helps to form the boundaries of Scarpa's triangle, Hunter's canal, and the popliteal space.

The general shape of the thigh is that of a truncated cone with its base above. Its contour varies with the amount of muscular development, the condition of contraction of these muscles, and the thickness of the subcutaneous fascia. Its median surface is marked by a furrow running from the inguinal fossa (fossa subinguinalis) to the inner side of the knee. This groove marks the boundary between the adductor muscles and the vastus internus muscle (M. vastus medialis). The sartorius lies

* The term thigh is defined in this manner in the Century Dictionary and is used in this sense by Cunningham, Quain, Morris, etc.

† Joessel: "Lehrbuch der topographischen Anatomie;" article on the *Thigh* by Huntington, in the first edition of this work; etc.

directly external to this, and the larger nerves and blood-vessels of the thigh are just median to this upon the adductor muscles. On the external surface (regio femoris lateralis) it is possible to see a furrow, unless the amount

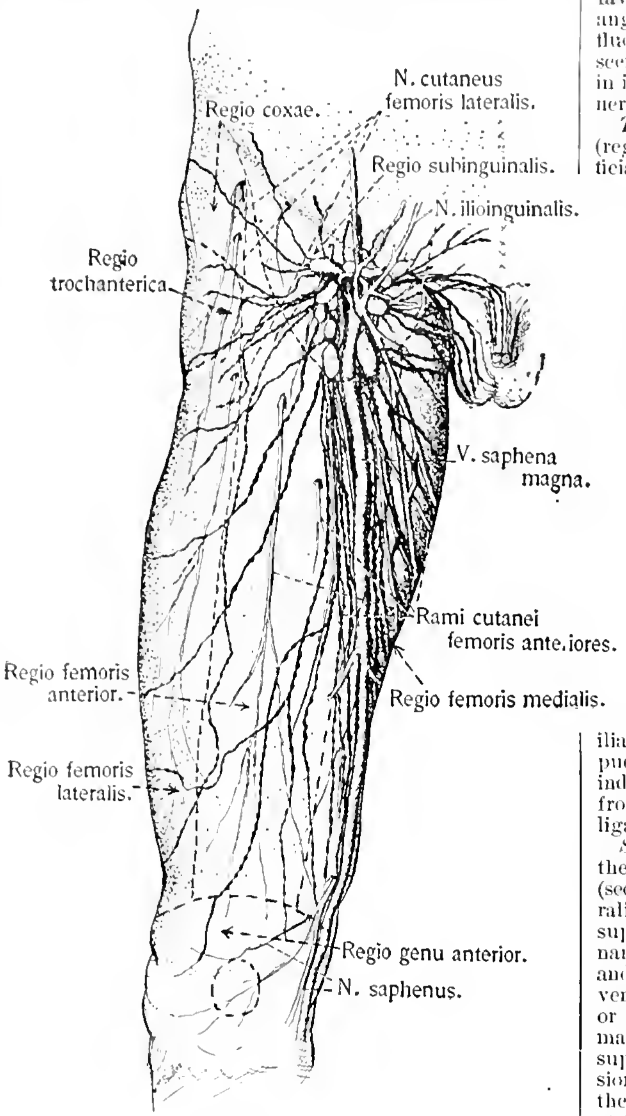

FIG. 4703.—Superficial Veins, Nerves, and Lymphatics on the Front of the Thigh. Only part of the lymphatic vessels is shown, in order not to make the figure too complicated. Drawn from the dissection and from photographs. The dissection was made by A. J. Price, Cornell University Medical College, Ithaca, N. Y. The regions are taken from Spalteholz's "Atlas of Human Anatomy."

of fat is so thick that it is hidden. It is caused by the intermuscular septum (lig. intermusculare externum) between the vastus externus (M. vastus lateralis) and the biceps (M. biceps).

On the median surface (regio femoris medialis) the gracilis muscle is assumed as a dividing line, although it does not form an easily recognized boundary.

The skin covering the thigh is very retractile, due to the loose subcutaneous fascia. It is relatively thick and covered sparsely with hair. Over the inguinal region it is thinner, and in new-born children and very stout people the secretion of the glands may cause irritation. It is attached rather firmly at Poupart's ligament (lig. inguinale).

The superficial fascia (fascia subcutanea) is usually quite thick and better developed in women than in men. It may be from 2 to 3 cm. thick over the femoral artery (A. femoralis) in stout persons, and it is also apt to be the favorite seat of fatty tumor, especially over Scarpa's triangle. It is nowhere very dense, and has little or no influence upon the progress of a superficial abscess, as is seen in the readiness with which pus reaches the surface in inguinal buboes. This fascia contains the superficial nerves, veins, lymphatic vessels, and glands.

The Superficial Lymph Glands.—In the inguinal region (regio subinguinalis) there are from nine to twelve superficial lymph glands that can usually be felt with the finger. From three to five are arranged in a row parallel to Poupart's ligament (glandulæ inguinales) and the others at right angles to it (glandulæ crurales) (see Fig. 4703). The glandulæ inguinales receive the vessels returning from the abdominal wall, perineum, and external genitalia. They are often the site of inflammatory processes in infections of the genital organs, and when they are enlarged from such a cause, they are known as buboes. The glandulæ crurales receive the vessels of the lower extremity. Swelling of the different sets of glands serves to indicate the region of infection and thus are an aid in diagnosis. In operating upon these glands for suppuration their intimate relations with the large veins, arteries, and nerves should be borne in mind. The deep lymph glands (usually two in number) lie under the femoral vein (V. femoralis) and receive vessels from the limb. Most of the large lymphatic vessels which supply the thigh and leg accompany the long saphenous vein (V. saphena magna) as shown in Fig. 4703.

Superficial Arteries.—The superficial arteries of the thigh that have been given definite names are all found in the inguinal region (regio subinguinalis). They are the superficial epigastric (A. epigastrica superficialis), the superficial circumflex iliac (A. circumflexa iliaca superficialis), and the external pudic (A. pudenda externa subcutanea). Their names indicate sufficiently well their position, and hemorrhage from them is usually easily controlled by compression or ligature.

Superficial Veins.—The principal superficial veins are the long saphenous (V. saphena magna) and its branches (see Fig. 4703). It empties into the femoral vein (V. femoralis) after passing through the fossa ovalis. The three superficial veins corresponding to the arteries already named (V. pudenda externa, V. epigastrica superficialis, and V. circumflexa iliaca superficialis) empty into the vena femoralis as it passes under the fossa ovalis, or one or more of these may empty into the vena saphena magna by separate openings. These veins are all well supplied with valves. The vena saphena magna is occasionally double, and is often the seat of varix, and is then very much enlarged and tortuous. It is also ligated at times in the inguinal region as a curative measure for varix at a lower level.

Superficial Nerves.—The principal superficial nerves of the regio subinguinalis and the regio femoris are the ileo-inguinal (N. ileoinguinalis), genito-crural (N. lumbo-inguinalis and N. spermaticus externa), the external cutaneous (N. cutaneus externus), the middle cutaneous (N. cutaneus medius), the internal cutaneous (N. cutaneus internus), and the cutaneous branches of the obturator (N. obturatorius).

The ilio-inguinal nerve receives most of its fibres from the first lumbar nerve. It emerges from the external abdominal ring and divides into terminal branches, which supply the skin over the adductor longus, and that of the scrotum in the male or of the labia majora in the female.

The crural branch of the genito-crural nerve (N. lumboinguinalis) is formed principally by fibres from the second lumbar. It is distributed to the skin as far as the middle of the thigh.

The external cutaneous nerve (N. cutaneus externus) arises also from the second lumbar. It ordinarily penetrates the fascia lata 2 to 3 cm. under the superior anterior spine of the ilium (spina anterior superior ossis ilii), and divides into anterior and posterior branches. The different branches often penetrate the fascia lata separately (Fig. 4703). The anterior branch goes to the side of the thigh, and the posterior branch goes to the skin of the side and back of the thigh.

The middle cutaneous (N. cutaneus medius) supplies a large area of skin over the median portion of the thigh and over the sartorius muscle.

The internal cutaneous nerve (N. cutaneus internus) accompanies the great saphenous vein (V. saphena magna) and sends branches to the median part of the thigh as well as the inner side of the leg.

The cutaneous branches of the obturator nerve (N. obturatorius) supply a small area of skin just above the inner condyle of the knee.

Fascia Lata—The fascia lata is the deep fascia of the thigh, and is composed of very strong fibrous tissues which completely envelop the thigh. Most of the fibres run in a circular manner, but toward the upper and outer side, where the fascia is thickest, the longitudinal fibres are especially well developed. The whole of the fascia lata forms a strong cylindrical tube containing the muscle of the thigh, and if it is broken at any point, the muscles project outward in a hernia-like fashion. It is attached above and in front to Poupart's ligament (Lig. inguinale), on the outer side and behind to the outer lip of the crest of the ilium, and on the inner side to the tuberosity and ascending ramus of the ischium, the descending ramus of the pubis and the symphysis pubis. Below, it is much thinner, and is continuous with the fascia of the leg. Above and to the side the fascia is divided into two layers, which enclose the tensor vaginæ femoris muscle (M. tensor fasciæ latæ). At this point the fascia is thickened, and runs downward like a tendon to the external tuberosity of the tibia. This thickening is known as the ilio-tibial band (tractus iliotibialis) or Maissiat's band. At the edge of Poupart's ligament the structures are further complicated by a division of the fascia lata into two layers and by the presence of the fossa ovalis. The fascia also divides and forms a sheath for the sartorius muscle. Between the fascia lata and the muscles there is a thin layer of areolar connective tissue, through which phlegmonous processes may extend under the fascia. From the inner side of the tube formed by the fascia two strong projections penetrate between the muscles of the thigh, and are attached to the lips of the linea aspera (Lig. intermusculare laterale et mediale) to form the intermuscular septa. The lig. intermusculare laterale follows the edge of the origin of the vastus externus muscle (M. vastus lateralis), and is inserted into the outer lip of the linea aspera. The groove which this forms in relatively thin subjects has already been mentioned, and it separates the vastus externus muscle from the biceps and the other extensors. On the posterior side of the thigh there is also a slip of the fascia lata that runs between the flexor group of muscles and the adductors. It joins the ligamentum intermusculare laterale, and is inserted with it into the external lip of the linea aspera, as seen in Fig. 4704. The ligamentum intermusculare mediale is fastened to the internal lip of the linea aspera, and divides the adductors and extensors. A part of it also takes part in the formation of Hunter's canal (canalis adductorius).

These fibrous intermuscular septa divide the muscles into three groups: 1. An anterior and lateral group, which includes the tensor vaginæ femoris (M. tensor fasciæ latæ), the sartorius (M. sartorius), and the quadriceps femoris (M. quadriceps femoris). 2. An inner or medial group, which contains the adductors and the gracile (M. gracilis). The femoral vessels run between the quadriceps femoris and the adductors; that is, between the anterior and inner divisions. 3. A posterior group containing the flexors (M. biceps, semimembranosus, and semitendinosus). The muscles of the thigh are very large and strong. Many of them are very long, and, in amputations involving them, it must be remembered that, other things being equal, the farther from its origin the muscle is divided the more marked will be its retraction. So in amputations of the lower part of the thigh more must be allowed for retraction than in amputations of the upper part. The position of the limb will also influence the retraction of the various groups; consequently it should be held in the same position during amputation that it is to rest in during healing. The muscles on the posterior and inner aspect of the thigh usually retract the most, and this difference may amount to 5 to 7 cm., and in amputations by the circular method the flaps should be cut so as to allow for this.

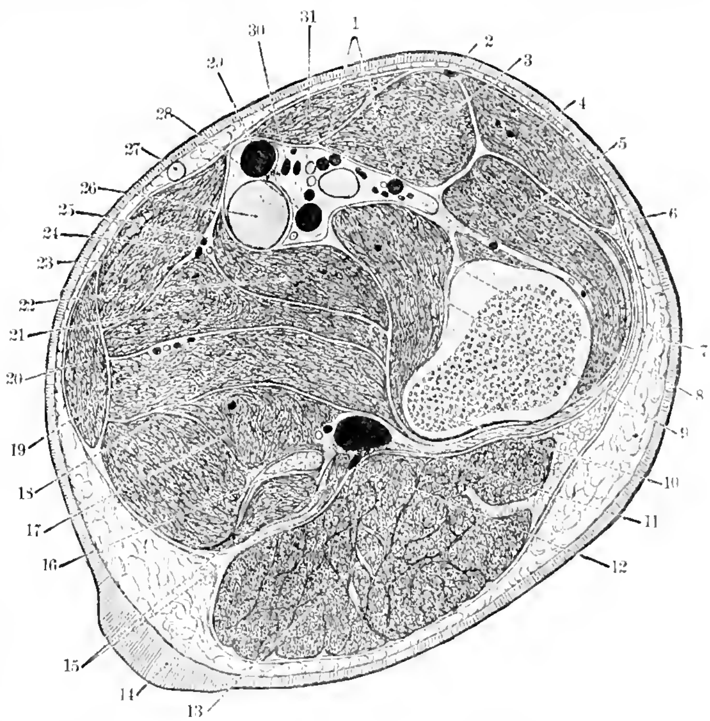

FIG. 4704.—(Toldt, Fig. 1019.) Cross-section through the Right Thigh taken at the Level of the Lesser Trochanter. Distal surface. 1,* A. * A., Arteria; N., nervus; M. musculus; V., vena.

ANTERIOR GROUP OF MUSCLES.—*Tensor vaginæ femoris* (M. tensor fasciæ latæ).—It is on the outer side of the hip. Its origin is on the anterior superior spine of the ilium (spina iliaca anterior superior) and the fascia lata. It is inserted into the ilio-tibial band (tractus iliotibialis), and its nerve supply is the N. glutæus superior.

Sartorius (M. sartorius).—It crosses the thigh in a

Thigh.

spiral manner and arises from the anterior superior spine of the ilium (spina iliaca anterior superior). It is in-

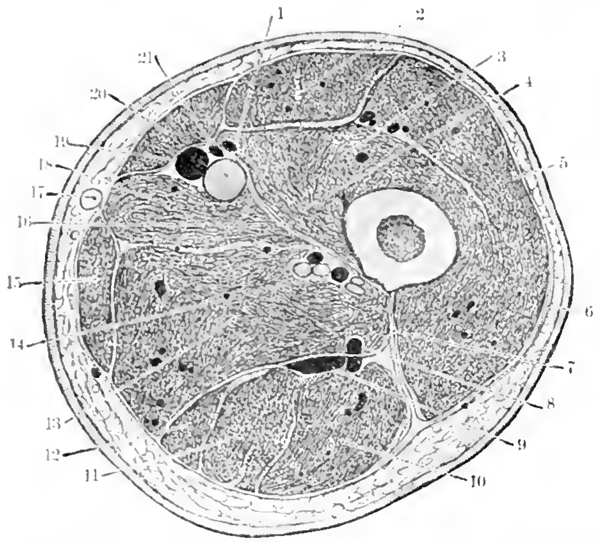

FIG. 4705. (Toldt, Fig. 1020.) Cross-section through the Right Thigh taken Somewhat Above the Middle. Distal surface. 1, V. femoralis; 2, M. rectus femoris; 3, M. vastus intermedius; 4, M. vastus medialis (lateralis); 5, M. vastus lateralis; 6, fascia lata (ilio-tibial band); 7, septum (or ligamentum) intermusculare laterale; 8, A. perforans; 9, N. ischiadicus (sciatic nerve); 10, M. biceps femoris; 11, M. semitendinosus; 12, semimembranosus; 13, M. adductor magnus; 14, A. profunda femoris; 15, M. gracilis; 16, septum intermusculare mediale; 17, V. saphena magna; 18, M. adductor longus; 19, A. femoralis; 20, M. sartorius; 21, V. femoralis.

serted into the tuberosity of the tibia. Its nerve supply is from the N. femoralis.

Quadriceps Femoris (M. quadriceps femoris).—This muscle consists of four portions (M. rectus femoris, vastus lateralis, vastus, intermedius, and vastus medialis).

Rectus Femoris (M. rectus femoris).—It arises from the inferior anterior spine of the ilium (Spina iliaca anterior inferior). It is inserted in common with the other divisions of the muscle into the common tendon.

Vastus Medius (M. vastus intermedius).—It arises from the anterior surface of the shaft of the femur and is inserted into the common tendon.

The *Vastus Externus* (M. vastus lateralis) arises from the intertrochanteric line, the lateral surface of the trochanter major, and the lateral lip of the linea aspera. It is inserted into the common tendon.

Vastus Internus (M. vastus medialis).—It arises from the inner lip of the linea aspera (labium mediale lineæ asperæ femoris) and is inserted in common with the other muscles into the common tendon that is attached to the patella. The four parts of the quadriceps femoris are all supplied by the anterior crural nerve (N. femoralis).

THE INNER GROUP OF MUSCLES.—The *pectineus* (M. pectineus) arises from the superior ramus of the os pubis and is inserted in the pectineal line on the lower part of the lesser trochanter of the femur. It is supplied by the anterior crural nerve (N. femoralis) and the obturator (N. obturatorius).

The *gracilis* (M. gracilis) arises from the inferior ramus of the os pubis and is inserted into the tuberosity of the tibia. It is supplied by the anterior branch of the N. obturatorius.

The *adductor longus* (M. adductor longus) arises from the superior ramus of the os pubis and is inserted into the inner lip of the linea aspera. It is supplied by the anterior branch of the N. obturatorius.

The *adductor brevis* (M. adductor brevis) arises from the anterior surfaces of the rami of the os pubis and is inserted into the inner lip of the linea aspera.

Adductor magnus (M. adductor magnus) arises from the anterior surface of the tuber ischium and the inferior ramus of the ischium. It is inserted into the inner lip of the linea aspera. It is supplied by the posterior branch of the obturator nerve (N. obturatorius) and the internal popliteal nerve (N. tibialis).

Scarpa's triangle (Trigonum subinguinale).—Scarpa's triangle is bounded above by Poupart's ligament, externally by the sartorius muscle and internally by the adductor longus muscle. It is important surgically on account of the number of important structures which it contains. Its apex is the point of election for ligating the femoral artery. It is here that digital pressure is applied in treating popliteal aneurism, and that a turniquet is applied in amputations involving parts of the limb below; a psoas abscess usually points here and femoral hernia appears in the upper part of it.

From the apex of Scarpa's triangle (trigonum subinguinale), on the surface of the upper part of the adductor magnus and piercing the lower part of it, we have a canal formed that carries the femoral artery, the femoral vein, and the long saphenous nerve. It is known as Hunter's canal (canalis adductorius). It is about 5 cm. long, and the upper opening is a crescent-shaped tendinous fold of the adductor magnus with the concavity directed upward. The inferior opening lies in the fleshy part of the adductor magnus, which aids in forming a tendinous border that forms a foramen known as the "adductor foramen." This opening serves to transmit the vessels to the popliteal space.

Femoral artery (A. femoralis) begins at the lower part of Poupart's ligament (Lig. inguinale) and ends at the adductor foramen, where it enters the popliteal space. For convenience of description the femoral artery is divided into three parts: (1) A superior segment in Scarpa's triangle; (2) a middle portion covered by the sartorius muscle, and (3) an inferior portion in Hunter's canal (canalis adductorius). Its general direction (see Fig. 4707) can be mapped out by a line drawn midway between the symphysis pubis and the superior anterior spine of the ilium to the posterior surface of the intercondylar process of the femur.

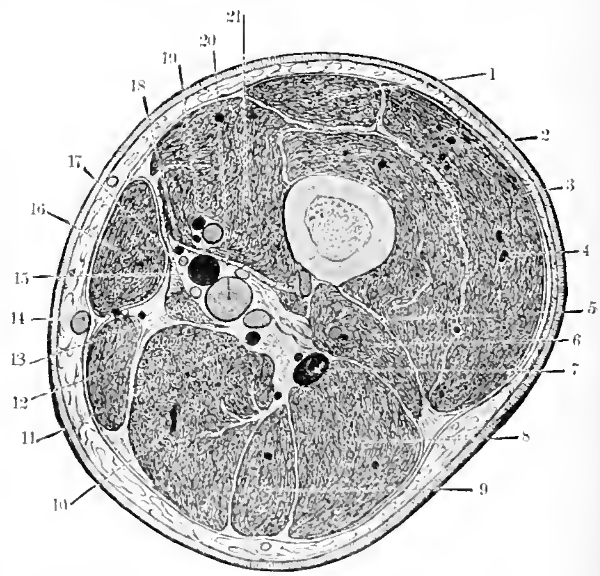

FIG. 4706.—(Toldt, Fig. 1021.) Cross-section through the Right Thigh taken Somewhat Above the "Adductor Foramen" through Hunter's Canal. Distal surface. 1, M. rectus femoris; 2, M. vastus intermedius; 3, fascia lata; 4, M. vastus lateralis; 5, septum intermusculare laterale; 6, M. biceps femoris; 7, N. ischiadicus (sciatic nerve); 8, M. biceps femoris; 9, M. semitendinosus; 10, M. semimembranosus; 11, A. perforans III.; 12, M. gracilis; 13, M. adductor magnus; 14, V. saphena magna; 15, canalis adductorius; 16, M. sartorius; 17, aponeurosis; 18, N. saphenus; 19, A. femoralis; 20, V. femoralis; 21, M. vastus medialis.

Superior Segment.—The superficial arteries given off from this division of the femoral have already been mentioned. The artery is covered here by the skin, the subcutaneous fascia and fat, the superficial lymph vessels and glands, and the fascia lata. The thickness of the fat in this region varies within rather wide limits, and this should be remembered in ligation. At the apex of Scarpa's triangle the artery lies just below and to the inside of the sartorius muscle, which is a good guide to its location. In ligating near the base of the triangle the femoral vein lies to the inside of the artery, but gradually comes to lie under it by the time it reaches the apex. No large nerves accompany this portion of the artery. The femoral nerve passes under Poupart's ligament in the sheath of the ilio-psoas muscle. The femoral artery is most easily compressed just where it emerges from under Poupart's ligament. The pressure should be downward and slightly upward to bring it against the bone. It can also be controlled at the apex of the triangle, and here the pressure should be downward and outward to bring it against the femur.

The *middle segment* of the femoral artery is the longest and is covered by the sartorius muscle throughout its length. The long saphenous nerve accompanies it, and although it is not in its sheath it must carefully be separated from the artery in ligation. The femoral vein lies under and to the outside of the artery. The position of the artery under the muscle makes it hard to control hemorrhage by digital pressure.

The *inferior segment* lies entirely in Hunter's canal (canalis adductorius). The femoral vein lies behind and to the outside and in the same sheath. The long saphenous nerve accompanies it and lies above and toward the inside, but not in the sheath.

The points usually selected for ligation of the femoral artery are, first, just below Poupart's ligament (ligamentum inguinale); second, at the apex of Scarpa's triangle (trigonum subinguinale); and, third, in Hunter's canal (canalis adductorius). In these operations the avoidance of the vein is the most important matter, although in Hunter's canal the long saphenous nerve must also be borne in mind. The muscular landmarks have already been given. The results of ligation of the femoral artery have been as follows:* In 31 cases in which the common femoral was ligated the mortality was 40 per cent.; hemorrhage 60 per cent. The superficial femoral has been ligated 204 times with a mortality of 50 cases.

Collateral Branches of the Femoral Artery.—The superficial branches of the artery have already been described. In addition to those enumerated it gives off the deep external pudic (A. pudenda subaponeurotica), but the largest artery supplying collateral branches is the profunda (A. profunda femoris). A knowledge of its exact position is very important in order that, in ligating the femoral artery, this branch may, if possible, be left undisturbed. It springs from the lateral and posterior side of the femoral artery from 3 to 10 cm. below Poupart's ligament and runs parallel with and outside of the more superficial femoral artery. It lies upon the iliacus, pectineus, and adductor brevis muscles, and then between the adductor longus and adductor magnus. It finally pierces the latter just above the adductor foramen as the fourth perforating artery (A. perforans IV.). A vein that empties into the femoral vein accompanies it for a short distance. It branches, soon after leaving the femoral, into the external circumflex (A. circumflexa lateralis), the internal circumflex (A. circumflexa medialis), and the three perforating arteries (Aa. perforantes). The external circumflex arises usually about 2 cm. from a point where the profunda leaves the femoral artery, but in a few cases it may come directly from the femoral. It divides into an ascending and a descending branch. The former goes to the upper part of the femur and anastomoses with the inferior gluteal (A. glutæa inferior), the superior gluteal (A. glutæa superior), and the deep circumflex iliac arteries (Aa. circumflexæ iliacæ profundæ). The descending branch supplies the vastus externus (M. vastus lateralis) and the vastus medius (M. vastus medialis intermedius).

The *internal circumflex artery* (A. circumflexa medialis) winds around the inner side of the femur at the height of the trochanter. It is first between the psoas and the pectineus and then between the obturator externus and the adductor brevis, and finally between the adductor magnus and the quadratus femoris. In this latter situation it

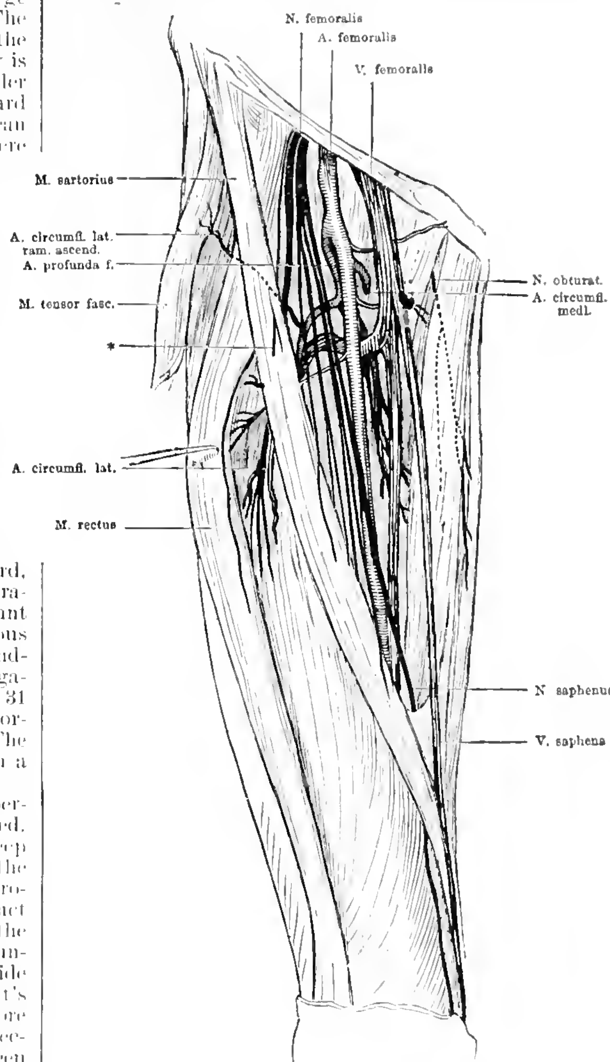

FIG. 4707.—The Surgical Anatomy of the Nerves, Veins, and Arteries on the Anterior Surface of the Thigh. (From Merkel-Henle.)

anastomoses with the sciatic artery (A. ischiadica), the external circumflex and the superior perforating to form the crucial anastomosis. It also sends a branch that pierces the capsule of the hip-joint and supplies the joint. In case of intracapsular fracture it is this branch which furnishes nutrition for the superior fragment.

The perforating arteries are usually three in number and pierce the adductor muscles near the linea aspera to supply the muscles on the posterior aspect of the thigh. The second one usually supplies the nutrient artery of the bone.

The inferior division of the femoral gives rise to the

* Joseph D. Bryant: "Operative Surgery," second edition, vol. i.

anastomotica magna artery (A. genu suprema) just before it pierces the adductor foramen. This artery divides into a superficial and a deep branch. The former runs on the vastus internus (M. vastus medialis) and aids in forming the plexus on the front of the knee. The deep branch penetrates the substance of the vastus internus and anas-

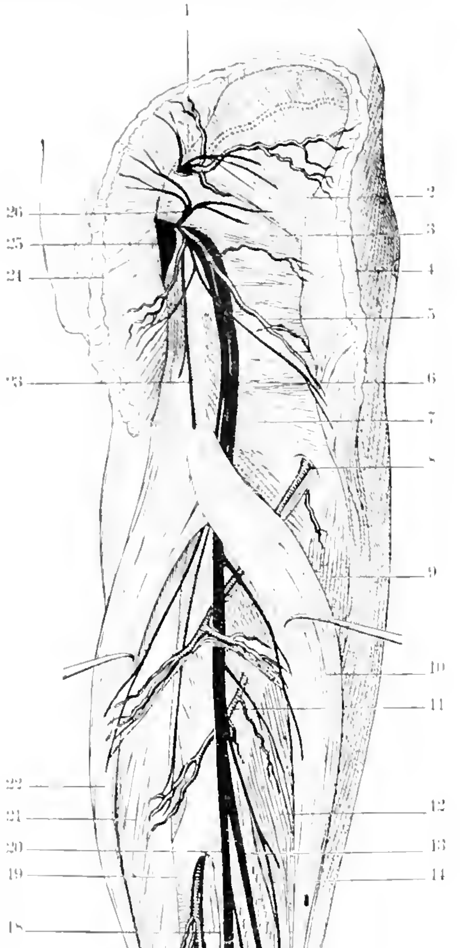

FIG. 4708.—The Relations of the Nerves, Blood-vessels, and Muscles of the Back of the Thigh. (Merkel-Henle.) 1, Superior gluteal artery and nerve; 2, M. gluteus medius; 3, M. pyriformis; 4, M. gluteus magnus; 5, inferior gluteal artery; 6, N. ischiadicus (sciatic nerve); 7, adductor muscles; 8, A. perforans I.; 9, M. biceps (short head); 10, M. biceps (long head); 11, A. perforans II.; 12, M. biceps; 13, N. peronæus communis (external popliteal); 14, superior articular branch from the external popliteal nerve; 15, inferior articular branch from the internal popliteal nerve; 16, N. cutaneus suræ lateralis; 17, N. cutaneus suræ medialis; 18, V. saphena parva (not well shown. It is represented by a part of the light area between the artery and nerve); 19, popliteal artery and vein; 20, N. tibialis (internal popliteal); 21, M. semimembranosus; 22, M. semitendinosus; 23, N. cutaneus femoris posticus (small sciatic nerve); 24, M. gluteus magnus; 25, pudic artery and nerve; 26, inferior gluteal nerve.

tomoses with the internal inferior articular branch of the popliteal (A. articularis genu superior lateralis) and supplies with them the knee-joint.

The *obturator artery* properly belongs to the pelvis, but it anastomoses with the internal circumflex artery (A. circumflexa medialis), and through the sciatic with the inferior gluteal. Through these connections it forms one of the most important channels of the circulation after ligation of the femoral.

Femoral Vein (V. femoralis).—The femoral vein lies to the inner (Fig. 4707) side of the artery and in the same sheath as it emerges from under Poupart's ligament (L. inguinale). As it passes through Scarpa's triangle (trigonum subinguinale) it passes spirally around the artery until at the apex it is directly posterior to it. In the lower part of the thigh it is below and somewhat to the lateral aspect of the artery. Two venæ comites are often present, and may be strongly developed.

Braun* has collected the following figures in regard to ligation of the vein: In 17 cases with the vein only ligated just under Poupart's ligament, 8 cases recovered and gangrene resulted in none. In 6 cases in which the ligation was concomitant with a removal of part of the vein, recovery resulted in 3 cases, gangrene in 2, and death in 1 case. In a series of 15 cases in which both the artery and the vein were ligated gangrene followed in 7.

Anterior Crural Nerve (N. femoralis).—The anterior crural passes below Poupart's ligament to the outside of the femoral artery (Fig. 4707). From this it is separated by the strong fascia iliaca. At a distance of from two to three centimetres under Poupart's ligament it divides into a number of branches to supply the skin and muscles of the anterior portion of the thigh (Figs. 4703 and 4707). The superficial branch runs under the sartorius, pierces and supplies that muscle, and pierces the fascia lata as the middle and internal cutaneous nerves. The deep branches supply the four portions of the quadriceps femoris muscle, and a small branch accompanies the internal circumflex artery to the pectineus. The anterior crural nerve also gives rise to the long saphenous nerve which accompanies the femoral artery through Hunter's canal.

Obturator nerve (N. obturatorius).—The obturator nerve reaches the inner side of the thigh by passing through the obturator foramen. It divides into a superficial and a deep branch. The superficial sends a small branch also to the pectineus, which thus obtains a nerve supply from two sources. It also supplies the adductor brevis and the abductor gracilis, and usually supplies the cutaneous branch to the skin over Hunter's canal and the lower part of the adductor longus muscle. The deep branches supply the obturator externus muscle and the adductor magnus. The obturator nerve thus supplies all of the muscles of this group except the part of the pectineus supplied by the anterior crural.

POSTERIOR SIDE OF THE THIGH.—The skin and fascia are sufficiently like those on the anterior side to need no special description. The small sciatic nerve (N. cutaneus femoris posterior) is found just under the fascia, and is distributed to the skin and fascia of the posterior aspect of the thigh, popliteal space, and leg.

The muscles found on the posterior side of the thigh have already been mentioned. They are the Mm. biceps, semitendinosus, and semimembranosus.

The *biceps* (M. biceps) springs from two heads. The long head takes origin in common with the semitendinosus from the tuber ischii. The short head has its origin in the middle third of the outer lip of the linea aspera. The two unite and are inserted into the head of the fibula. The long head is supplied by the internal popliteal nerve (N. tibialis), and the short head by the external popliteal (N. peronæus communis).

The *semitendinosus* (M. semitendinosus) has its origin on the tuber ischii and is inserted into the inner tuberosity of the tibia. It is supplied by the internal popliteal nerve (N. tibialis).

The *semimembranosus* (M. semimembranosus) arises by a long flat tendon from the tuber ischii, and is inserted into the inner tuberosity of the tibia beneath the semitendinosus. It is supplied by the internal popliteal nerve (N. tibialis).

The *great sciatic nerve* (N. ischiadicus).—This is the

* Braun: Archiv f. klin. Chirurgie, Bd. 37, Heft 3.

largest nerve in the body. It emerges under the gluteus maximus muscle and runs downward to the middle of the popliteal space (Fig. 4708). After emerging from under the gluteus maximus it is covered by the long head of the biceps. Between these flexor muscles it is buried in loose fatty connective tissue, which forms an easy path for burrowing pus from abscesses that have their origin usually in the pelvis. In this way the pus may reach the popliteal space. A line drawn from a point a little toward the median side of the centre of a line drawn from the great trochanter to the tuber ischii, to the middle of the popliteal space will lie over the nerve, and it is available as a guide in operations below the gluteofemoral crease. The nerve divides a little below the middle of the thigh into two branches, the internal (N. tibialis) and the external (N. peronaeus) popliteal branches. The great sciatic nerve supplies the muscles of the back of the thigh, as has already been described. Its size and the number of its sensory fibres make it an important nerve in causing shock. Operative procedures involving this nerve may be made less serious by the use of cocaine locally, or by manipulations that reduce the mechanical irritation to a minimum.

Arteries and Veins.—The superior portion of the back of the thigh is supplied by the inferior gluteal artery (A. glutæa inferior) (Fig. 4708). It anastomoses with the internal and external circumflex arteries and the perforating arteries. The perforating arteries (Fig. 4708) are usually three in number and supply the muscles on the back of the thigh. The deep veins of the posterior side accompany the artery.

The Skeleton of the Thigh.—The shaft of the femur is bent in the form of a bow anteriorly. This outward and anterior curve gives the adductor muscles (the adductor magnus especially) a greater angle, and this arrangement of the muscle is the cause of the lower fragment often being pulled upon the inner one in fracture. In old age the spongy bone in the neck of the femur often undergoes fatty degeneration and disappears. This is the cause of the increased frequency of fracture at this part of the bone in old age. It occurs oftener in women than in men, owing to the fact that the angle is more obtuse in women than in men, and so the strain has a greater mechanical advantage. *Mervin T. Sudler.*

THILANIN.—This title is given to a compound of sulphur and lanolin, which is said to contain three per cent. of sulphur, but whether in combination with the cholesterin or with the fatty acids is undetermined. It was introduced by Dr. Edmund Saalfeld, at the third Congress of the German Dermatological Society, as being devoid of any irritating properties and useful in cutaneous affections. *Beaumont Small.*

THIOCOL, guaiacol-sulphonate of potassium, $C_6H_3.OH.OCH_3.SO_3K$, is a white, odorless crystalline powder with a faintly bitter taste. It is soluble in water or diluted alcohol, but not in strong alcohol, ether, or the fatty oils. Its aqueous solution is turned violet blue by ferric chloride.

Thiocol, being a soluble compound of guaiacol, has the medicinal properties of this substance; but its taste is not disagreeable, it is unirritating to the stomach, and it does not "repeat" after ingestion. Being soluble it is easily administered and rapidly absorbed. Schwarz states that 15 gm. (℥ ss.) a day have been taken with no unfavorable symptoms. The results in tuberculous patients, as noted by Mendelssohn, Braun, Moir of Edinburgh, and many others, are increased appetite, lessened cough and sputum, disappearance of night sweats, moderation of the diarrhœa, and general improvement. The employment in whooping-cough and respiratory troubles other than tuberculosis has met with ardent advocates. In enteritis Schnirer studied its action in thirty-eight cases, and placed it among the valuable antidiarrhœic remedies. For children he recommends ℞ Thiocol, 0.5 c.c. (♏ viij.); syrup of orange peel, 10 c.c. (ʒ iiss.); water to make 60 c.c. (℥ ij.). Sig.: A teaspoonful every two hours. For the adult, thiocol may be administered in capsule, cachet, tablet, or solution. The dose is 0.5 gm. (gr. viij.) three times a day, gradually increased.

A ten per-cent. syrup of thiocol is marketed under the name of "*Sirolin.*" *W. A. Bastedo.*

THIOCYANATES. See *Sulphocyanides.*

THIOFORM is a basic bismuth di-thio-salicylate. It is a yellow, odorless powder containing seventy two per cent. of bismuth oxide, and is used as a dusting powder or ten-per-cent. ointment in place of iodoform. There are good reports of its employment in eczema.

W. A. Bastedo.

THIOGENOL is a compound of sodium sulphonate containing ten per cent. of sulphur. It is readily soluble in water and alcohol and is used by Jaquet in two-per cent. solution as an injection in gonorrhœa, and both pure and in twenty-per-cent. ointment for dermatitis and prurigo. It is an ichthyol substitute. *W. A. Bastedo.*

THIOL.—An artificial ichthyol, prepared by treating with sulphur the hydrocarbons having a specific gravity between 0.890 and 0.900, that are obtained from coal tar. The latter differs from ichthyol by the absence of much organic matter that supplies its objectionable qualities, their presence, it is claimed, being of no therapeutic value. After the thiol has been separated it is evaporated to an extract—*thiolum liquidum*, or to complete dryness—*thiolum siccum*.

Liquid thiol is a thin, brownish, neutral liquid, with a specific gravity of 1.080 to 1.082 at 60° F. It has a feeble bituminous odor, not disagreeable. It forms a clear solution with water, especially if glycerin be added. It is not very soluble in alcohol or ether. Aqueous solutions froth abundantly when shaken; they are not affected by the addition of strong alcohol, but soda, dilute acids, or metallic salts cause a precipitate. Dry thiol, which forms forty per cent. of the liquid form, is a dark brown or blackish mass, sometimes formed in scales, which, when heated, burns away entirely, leaving no residue. The advantages claimed for thiol over ichthyol are, that it is really a purified form of the latter, that it is devoid of the disagreeable odor, and does not stain the linen or clothing, is less irritating, and more definite in composition. The therapeutic use of thiol is the same as that of ichthyol.

Although the pure drug may be applied without causing any irritant action, a ten-per-cent. preparation is generally sufficient for all purposes. The powder may be combined with powdered starch; or aqueous or glycerin solutions may be prepared. For wounds a five- or ten-per-cent. solution in collodion is very serviceable. An ointment may be made with vaselin or lanolin.

For inflammatory diseases, and in gynecological practice, its action is increased by internal administration in addition to its local use. The dose is one grain and a half, which may be repeated up to five times a day. It is given in cachets, in pill form, or in solution in wine.

Beaumont Small.

THIOLINIC ACID, sulphurated linseed oil, thiolin, is a dark green semi-solid mass of peculiar mustard like odor, containing about fifteen per cent. of sulphur. It is insoluble in water and soluble in alcohol, and is employed as a succedaneum for ichthyol. *W. A. Bastedo.*

THIOPHENE.—C_4H_4S. This is a sulphur holding hydrocarbon, contained in coal tar benzin. In the pure state it is a colorless, clear, volatile oil, boiling at 184° F., of slight odor, and will not mix with water. Thiophene itself is not employed as a therapeutic agent, but two preparations have been introduced—*sodium thiophensulphonate* and *thiophene di-iodide*.

Sodium thiophensulphonate, $C_4H_3SNaSO_3$, is a white crystalline powder, containing thirty-three per cent. of sulphur, and having a slight but unpleasant odor. Used as a dusting powder, or applied as an ointment, ten per cent., with equal parts of lanolin and vaseline, it has proved of much service in all forms of prurigo. A lead salt has also been prepared and used with success in the same disorder.

Thiophene di-iodide, $C_4H_2I_2S$; contains seventy five per cent. of iodine and 9.5 per cent. of sulphur. It forms in fine crystalline plates, insoluble in water. The di iodide has been proposed as a substitute for iodoform, as it has a less unpleasant odor. *Beaumont Small.*

THIO-RESORCIN, $C_6H_4(SH)_2$, is a yellowish-gray insoluble powder made by fusing together resorcin and sulphur. It is a substitute for iodoform, and has been employed in skin and scalp diseases in ten-per cent. ointment. *W. A. Bastedo.*

THIO-SALICYLIC ACID, $C_6H_4.SH.COOH$, is salicylic acid with an oxygen atom replaced by sulphur. It is used like salicylic acid as an antiseptic. *W. A. Bastedo.*

THIOSAPOL, a soda soap (hard soap) containing about ten per cent. of sulphur in combination, is used in the treatment of skin diseases. *Thiosavonal* is the corresponding potash soap (soft soap). *W. A. Bastedo.*

THIOSINAMINE (*Allyl-Sulpho-Carbamide*).—This long known chemical compound has been recently introduced as a drug possessing valuable therapeutic properties. It is obtained by the action of alcohol and ammonia upon the ethereal oil of mustard, which forms a basic compound with the following formula, $C_3H_5.NH.NH_2.CS$. It forms in colorless and odorless prismatic crystals, having a bitter taste, and is readily soluble in water, alcohol, and ether.

Thiosinamine has attracted attention on account of its reputed resolvent action upon scar tissue. When injected into tissue causing deformity and disability by contracture, it is said to produce a softening and relaxation which allow the part to become free and pliable. Numerous cases of fingers and limbs that were beyond the use of the knife are reported to have been almost perfectly restored. This effect was announced by Dr. H. von Hebra, Jr., of Vienna, in 1892, at the International Congress on Dermatology. He recommends that a fifteen-per-cent. alcoholic solution be prepared, and that two injections a week be used. It has been used with success for the purpose of relaxing the cicatricial tissue of urethral strictures. It has also been used in gynecological practice to relieve the symptoms arising from the effects of perimetritis and inflammatory troubles about the appendages. In addition to its action on cicatricial tissue, it causes a decided increase in diuresis and diaphoresis, and exerts a powerful tonic effect upon the system, in consequence of which it was thought to have a beneficial resolvent action upon local tuberculosis. Upon chronic enlargement of lymphatic glands its effect was very marked. In a number of cases of lupus it was noticed to exert a beneficial action. It has been reputed as acting favorably upon corneal opacities and deafness from thickening of the membranes. The injections are made in the interscapular or gluteal regions. No constitutional effect followed the injections, but a local reaction set in after a few hours, causing redness, tension, and swelling of the affected part. A ten per cent. solution in glycerin and water may be used. The dose is from one to three grains. *Beaumont Small.*

THIRD NERVE.—See *Cranial Nerves*.

THIRST.—1. DEFINITION AND CLASSIFICATION.—Gould defines thirst as "a state manifested by a desire for drink." The Century Dictionary defines thirst as "the uncomfortable sensation arising from the want of liquid nutriment; the uneasiness and suffering occasioned by want of drink; vehement desire for drink." From these definitions it becomes clear that thirst, as understood by the lexicographers, expresses first, *a condition of body*; second, *a sensation*; third, *a desire*. The condition is the need of water; the sensation is one of dryness of the mucous membranes, especially those of the mouth and fossæ. Following this sensation there is a natural desire for the needed water to allay the sensation.

In classifying thirst among the sensations, it is necessary to remember that all sensations may be divided into objective and subjective, the objective sensations being those which arise from stimuli caused by natural substances or forces acting upon sensory nerve ends; while subjective sensations are the re-experiencing of objective sensations without any physical basis. Subjective sensations are illusory and are experienced in dreams and in certain unusual conditions of the nervous system. Objective sensations may be subdivided into two classes: First, those caused by objects or forces outside of the body, as vision is caused by light entering the eye from without, or hearing, by sound waves entering the ear from without.

The second class of objective sensations may be called *indirect objective* or *auto-objective*. This class of sensations includes hunger, thirst, suffocation, pain, fatigue, etc. It will be noted that these auto-objective sensations all arise from different conditions that exist within the system, the first three named being manifestations of needs of the body for more matter, the last two, manifestations of overstimulation or overwork.

2. PHYSIOLOGICAL CONSIDERATIONS.—In order to get a clear idea of thirst, it is necessary for us to consider briefly the need of the system for water. The first need arises in the process of digestion within the alimentary tract and absorption from the alimentary tract. Nearly all of the digestive processes are hydrolytic cleavages which involve not only the incorporation of molecules of water into new combinations, but which combinations take place far more readily in the presence of abundant water. Absorption takes place slowly and with difficulty if the digested products are not thoroughly diluted with water. Once the food is absorbed and passes into the circulation, the proportion of water in the blood must remain fairly constant, otherwise the diffusion of blood and lymph plasma carrying nutrition to the tissues is interfered with. The metabolic processes in general involve either the incorporation or the liberation of water molecules, and these processes take place freely in the presence of an ample supply of water only. Secretion and excretion from glandular epithelia are scanty except for an abundance of water in the blood.

These various needs of the system for water are manifested, first and most apparently, by decreased water in secretion and excretion. This decrease of the water contents of secretion and excretion is most noticeable to the subject in the drying of the mucous membranes of the mouth and throat. This, in fact, is the sensation usually experienced in thirst and associated with that term. There is also, however, an increased specific gravity of the blood and lymph followed by what may be termed a tissue thirst, or a need of the active tissues of the body for water. This leads to a classification of thirst into *local* or *external thirst* as experienced in the mouth and throat on the one hand, and *general* or *internal thirst* experienced by the tissues of the body, and appealing to the consciousness in a rather vague feeling of lassitude difficult to describe, but quickly relieved by a copious draught of cool water.

The nervous mechanism of the sensation of thirst is obscure. Sherrington, in his chapter on sensation (Schaefer's "Textbook of Physiology," vol. ii., p. 992) refers to a thirst centre located in the medulla in association with the nuclei of the ninth and tenth nerves, the cerebral connections passing from this centre upward, the afferent impulses coming from the distribution of the glossopharyngeus and vagus nerves in the mouth, pharynx, œsophagus, and stomach. If we accept this theory, we are driven to the alternative of supposing that the thirst centre, wherever that may be located, is influenced by the blood supplying the centre. This theory, while it might account for general tissue thirst, could not account for the local thirst arising from the dryness of mucous membranes.

Local thirst may be abated or allayed by local application of water to the mucous membranes affected. If the local thirst is, however, a local manifestation of the general condition, this method of allaying it will only be temporary and the sensation will recur a few moments after the application. General thirst may be allayed by intravenous injection of normal saline solution; by introduction of water into the stomach through a stomach tube, or by the introduction of water into the rectum. In all of these cases the water is rapidly absorbed and transported to the thirsty tissues and general thirst is thus assuaged, followed rapidly by an alleviation of local thirst. Had the water been taken in the usual way of drinking, the local thirst would have been temporarily allayed, incidentally upon the passage of the water over the mucous membranes, and this would have been followed presently by a moistening of these tissues from within by the more copious secretions. Variations of the above usual conditions may be noticed. Meteorological conditions, such as a high temperature or low humidity, will cause a profuse perspiration followed by a general increased demand for water. Muscular exercise will have a similar effect. Diet, if rich in salts or sugars, will lead to a demand for water to dilute the solutions to the normal specific gravity, while the free use of diuretic diets, as lemons or oranges, will lead to a depletion of the water of the system and be followed by thirst.

3. Pathological Considerations.—In its pathological relation thirst is called *polydipsia*, *dipsosis*, or *dipsis*. It may be said, in passing, that *polydipsia ebriaria* (thirst for intoxicants) is not real thirst in any proper use of that term, though "thirst" is much used to express a desire for alcoholic drinks. Thirst proper is a desire for water.

Polydipsia is associated with many diseases as a symptom.

First, in such diseases as diarrhœa or cholera (in which diarrhœa is a prominent symptom) much water is carried off in watery stools. In diabetes insipidus water is lost in polyuria. In hemorrhage water is lost with the blood. In all of these cases there is extreme thirst as a secondary symptom or condition. This extreme thirst may be abated with frequent draughts of cool water and a free use of liquid diet.

Second, in diabetes mellitus the thirst is a secondary symptom caused by the increased sugar in the blood, which in turn leads to a demand on the part of the tissues for water to lower the specific gravity of the blood.

The polyuria of diabetes mellitus is secondary to the polydipsia, while the polydipsia of the diabetes insipidus is secondary to the polyuria.

Third, in another class of pathological conditions belongs hysterical polydipsia, which is as inexplicable as are other symptoms that may be manifested in hysteria.

4. Dietetic and Therapeutic Considerations.—The adult of average size requires about two litres of water each twenty-four hours to make good the loss by excretion and evaporation. About one-half of this requirement is supplied by the average diet, leaving one litre (about four glasses) to be taken as a beverage. Many adults take much less than this quantity. But many adults take too small an amount of water; few take too much. There is a growing belief in the medical profession that water is a most valuable agent for flushing out accumulating excretory material from the tissues.

The sense of thirst may readily become perverted and thus fail to fulfil nature's plan as an admonisher of a need for water. Such a condition results in malnutrition.

Winfield S. Hall.

THIRY-VELLA FISTULA.—See *Succus Entericus*.

THIURET, $C_8H_7N_3S_2$, is a sulphur compound which is used as a substitute for iodoform. It is a light, odorless powder insoluble in water and soluble in alcohol and ether. In warm alkaline solution it sets free its sulphur. The compounds with hydrochloric, hydrobromic, salicylic, or sulpho-carbolic acids are somewhat soluble in water.

W. A. Bastedo.

THOMASVILLE, GEORGIA.—This well-known and desirable winter resort is situated in the southwestern portion of the State, not far from the Florida line, and about one hundred and sixty miles from the Atlantic coast, and fifty-three miles from the Gulf of Mexico. It lies in the great southern pine belt, and, like Summerville, Aiken, and other resorts in this belt, is in a forest of pines, on sandy soil, and at a distance from any body of water. It has an elevation of 380 feet above sea level, which is the highest ground in that part of the State.

The town is an attractive one, with a population of about seven thousand, with broad and shady streets, a park, churches of various creeds, an opera house, colleges, and many good schools. The place is well lighted, there is a system of sewerage, and there are water-works supplying the whole city from an artesian well nineteen hundred feet deep. The natural drainage of the town is also excellent.

The surrounding country is undulating, and besides corn and cotton, grapes are produced in abundance, and the famous "Le Conte" pear. Many other fruits are also grown here, such as peaches, plums, apples, strawberries, figs, and watermelons; and there is a profusion of flowers.

The accommodations are abundant and good, there being several first-class hotels, a large number of good private boarding-houses, and cottages and rooms to rent by the season or month for housekeeping purposes.

The tuberculous invalid, however, contemplating a temporary residence at Thomasville, must be warned of the difficulty of obtaining accommodations in the hotels or boarding-houses. As a rule such patients are not received, simply because invalids suffering from diseases other than tuberculosis, and tourists in general, will not frequent hotels or boarding-houses where consumptives are taken. The only alternative for the unfortunate tuberculous individual seems to be renting a cottage and establishing a temporary home.

The climate tempts to an almost constant out-of-door existence, and one of the chief attractions of the place is to be found in the beautiful drives through the pine forests. The roads radiate from the town in all directions, and are smooth and solid, being well adapted to cycling. A short distance from the city is the Country Club, with extensive grounds and a club-house. There are also golf links and a pack of fox hounds.

The resort is filled with visitors in the winter and early spring, and is also a stopping-place for those going to or coming from Florida. It is visited by those seeking merely change and recreation as well as by those seeking health. The hospitality of the people is particularly noted.

The climate, as will be seen from an inspection of the accompanying chart, is a comparatively dry one; its winters are warm without the enervating influences of the Florida coast resorts; "it is to a marked degree exempt from severe winds, and there is always a great preponderance of sunshine and of days which admit of out-of-door exercise on the part of the invalid."

The diseases for which such a climate is to be recommended are particularly the various catarrhal affections of the respiratory passages, and incipient or early pulmonary tuberculosis in individuals who have not the resisting power to undergo with advantage the cure in the high altitudes. Moreover, it is a favorable winter climate for very many conditions which require a mild, sunny climate, where outdoor life can be indulged in without great demands upon one's vitality. The feeble, young, or old, those temporarily weakened by sickness or hardship, can lead here a quiet, comfortable existence and, when possible, regain their former maximum of health and strength.

Access from the north to Thomasville is easy and ex-

THOMSEN'S DISEASE. See *Muscle, Pathology of.*

THORACIC DUCT.—The thoracic duct, the large lymph channel of the body, runs from the receptaculum chyli to the left side of the neck, where it terminates at the angle of junction of the left subclavian and internal jugular veins. The receptaculum chyli is located on the anterior surface of the body of the second lumbar vertebra, and is a dilatation of the lower end of the duct, into which empty a large number of lymphatics and lacteals from the lumbar region and the organs of digestion. This pouch is not always present, its place being sometimes taken by a network of lymph vessels which unite to form the duct. This vessel has its course upward and to the right, on the anterior surface of the lumbar vertebræ, to the right of the aorta, in company with which it passes between the two crura of the diaphragm and enters the thorax. It now ascends on the dorsal vertebræ, lying between the thoracic aorta and the right vena azygos, and behind the posterior parietal pleura. At the fifth dorsal vertebra it curves to the left, and passing behind the transverse portion of the aorta, runs upward and to the left behind and slightly internal to the left subclavian artery. Passing into the neck, it now lies on the anterior surface of the scalenus anticus muscle, under the deep layer of fascia that lies over the muscle. The point to which it rises in the neck varies considerably. It may pass outward to the angle of junction of the subclavian and internal jugular veins, and empty by a single trunk into the veins as they unite to form the left innominate, never rising above the level of the upper border of the subclavian vein. This is the form which is least likely to be injured in surgical operations, as it is well protected by the deeper structures. It may ascend on the anterior surface of the scalenus anticus, as high as 6–6.5 cm. above the upper border of the first rib, or to the level of the middle of the thyroid gland. In these cases it curves downward and outward and frequently splits into a number of branches which may re-unite and form a single trunk, or may empty separately into the subclavian or internal jugular veins, or both; into the vertebral or the transversalis colli veins; or into any combination of these veins, depending upon the number of branches in the particular instance. After injecting and dissecting some fifty specimens, I am unable to state any fixed rule for the distribution of the cervical portion of the duct, or to formulate any systematic classification of the different variations of termination. It can, however, be said that, as a general rule, the higher the duct rises in the neck, the more likely it is to have terminal branches. When the duct is a single trunk, it generally lies low. The cervical portion is the only part that is of practical importance, from a surgical standpoint, as it is the only part that is exposed to surgical interference. The terminal portion of the duct, or the terminal divisions, if there are any, will always be found on the anterior surface of the scalenus anticus, or under the deep fascia covering the muscle, behind and internal to the last portion of the internal jugular vein. Where the duct rises high in the neck and presents many branches, it very frequently has a branch lying behind the clavicle, in the thorax, and emptying into the posterior portion of the

FIG. 4709.—Cervical Relations of the Duct in the Neck, showing a terminal arrangement frequently seen. The duct here divides into three terminal branches, emptying into the internal jugular (erroneously labeled "external jugular" in the cut), the subclavian and the transverse cervical veins, with a cross branch connecting the first and second branches. (From a drawing by G. R. Egeland, from a dissection from the dissecting room of the Northwestern University Medical School, Chicago.)

subclavian vein. In case of injury to the cervical portion of the duct, this branch alone would suffice for furnishing collateral circulation.

Anomalies.—Besides the multiple endings of the duct, which are so common as to be normal, the most frequent anomaly observed is that of the duct terminating in the right subclavian vein inside of the left. This has been frequently observed and is generally found associated with vascular irregularities, especially with absence of the innominate artery, with the right common carotid and subclavian arteries springing directly from the arch of the aorta. In such cases the thoracic duct takes the place of the right lymphatic duct, and the left duct has a corresponding course and relation usually found in the normal duct on the right side. Less frequently seen is a duct, double throughout, one portion going to the subclavian vein on each side, the two ducts being connected by numerous cross branches. Occasionally one finds a duct, single as far as the fourth or fifth dorsal vertebra, then dividing and sending a branch to the vein on each side. Cases of anomalous course or distribution have been reported by Thompson, Watson, Cruickshank, Krause, Paturban, Thomson, and Brinton. Thomson suggests that there are probably developmental reasons for these anomalies.

Physiology.—The function of the thoracic duct is to convey the chyle from the digestive system and the lymph from the lumbar glands to the blood of the right heart. It is not known what constitutes the force that pumps the lymph from the abdominal cavity to the termination in the left side of the neck. Weiss found that the pressure in the duct was equal to from 9 to 15 mm. of mercury. The flow of blood through the arch of the aorta, the action of expiration and inspiration, and the motion of the heart, as well as intrathoracic pressure, and the force of the flow of blood in the left innominate vein, are probably all factors in producing and maintaining the lymph flow. I have repeatedly found it impossible, in the cadaver, to inject the duct from the abdominal cavity until the heart and lungs were removed.

As to the composition of the fluid found in the duct of the human being, several analyses have been made. Rees, in 1843, analyzed the lymph taken from the duct of a recently executed criminal. Seyler took the contents of a pleuritic effusion caused by the rupture of a duct in the thorax. Hasebrook obtained and examined the fluid of a chylous pericardial effusion. Paton, in 1890, made three analyses of the fluid obtained from a chylous fistule following an operation for sarcoma of the neck. As it is impossible to say how greatly the chyle may be modified by absorption from a serous cavity, the results of the second and third observers are somewhat discredited. Rees and Paton, therefore, are best worthy of consideration. Their analyses gave the following results:

	Rees.	Paton.
Water	904.8	951.6
Solids	95.2	51.7
Organic	90.8	41.91
Proteids	70.8	12.53
Fats	9.2	26.06
Inorganic	4.4	6.49

In regard to the rate of flow, Paton found that it averaged from 1 to 3 cub. cm. per minute, or from 1,584 to 4,752 cub. cm. per twenty-four hours. The weight of the patient was 60 kgm. Therefore the flow was from 2.64 to 7.93 cub. cm. per 100 kgm. of body weight.

THORACIC DUCT, PATHOLOGY OF.—Not many pathological conditions of the thoracic duct have been reported. This may be explained in part by the fact that anastomoses are frequently present, and consequently the symptoms which would have been caused are masked or absent. At other times the region in which the duct lies is examined at autopsy very superficially if at all, and consequently some pathological conditions are not seen.

Anomalies.—Anomalies of the thoracic duct are not uncommon. The duct may lie on the right side of the vertebral column; it may have two or three outlets into the subclavian vein, or it may be double throughout its entire course. In other cases the main trunk may divide to form a plexus of lymph vessels in the posterior mediastinum, the radicles uniting to form a single trunk which empties into the subclavian vein in the usual manner. Besides these more common varieties, other anomalies may occur, that reported by Svitzer[45] being one of the most peculiar. In his case the duct partially encircled the aorta and emptied into the left subclavian vein.

Hemorrhage.—Hemorrhage into the duct may result from trauma to the duct, or may be present in severe anæmias or leukæmias. In cases of congenital or acquired hæmophilia in which retroperitoneal hemorrhages occur, or in cases of injuries to the intestines, the contents of the duct may contain a variable amount of blood. In any case in which blood is present in the duct it may remain fluid, but if the quantity becomes very great, coagulation may result and a large clot form, which may cause obstruction.

Thrombosis.—According to Leydecker[1] thrombosis of the thoracic duct may follow lymphangitis, trauma, pressure from tumors, aneurisms, and exostoses of the vertebræ, or may accompany lesions of the heart valves.

Usually these thrombi are recent, as was the one seen by Turney.[2] The patient gave a history of chylothorax and chylous ascites, and at autopsy Turney found a thrombus at the mouth of the duct, extending downward a short distance and completely blocking the lumen. Below the obstruction the duct was greatly dilated, as were all its radicles. All the superficial lymphatics of the upper extremity were also dilated.

Oppolzer[46] reported a case in which no history nor signs of chylothorax nor chylous ascites were given. The patient had a valvular lesion, and at autopsy Oppolzer found that a clot obstructed the mouth and, for a short distance, the lumen of the duct.

Cayley reported a case in which a similar pathological condition was found. The patient was a young man, nineteen years old, whose chief symptoms were constipation and pain in the abdomen. He gave signs of chylous ascites, but none of chylothorax. Further examination showed the presence of a large retroperitoneal tumor which at autopsy proved to be a greatly dilated receptaculum chyli and its radicles. The thoracic duct was dilated, and at its mouth Cayley found a clot which closed the outlet of the duct.

In other cases the thrombi undergo partial or complete organization, so that the lumen may become partially or wholly occluded by a mass of connective tissue canalized by new blood and lymph vessels. Such a condition was seen by Heller.[3]

Retrograde Changes.—The only case of necrosis of the thoracic duct which has been reported as yet is the one quoted by Noehler,[4] and in the light of modern pathology his diagnosis and autopsy findings might be questioned. He diagnosed the case as "malignant epidemic fever," and at autopsy, a few hours after death, found what he called a "gangrenous thoracic duct."

Here might be mentioned two cases which are interesting, in that they show changes analogous to those found in old sclerotic arteries. Brown-Cheston[16] and Assalini[17] have reported a case each, in which they found a thoracic duct, the wall of which was converted into a calcified tube.

Aneurisms and Cysts.—Many dilatations of the thoracic duct have been mistaken for aneurisms or cysts. Some of these could be explained easily by dilatation caused by some obstruction to the flow. On the other hand, cases of dilatation have been reported which could not be explained by any increased pressure within or without the duct. Such conditions are comparable with the formation of aneurisms of arteries and veins, in that the walls become atrophied and a localized dilatation follows. Cases showing this condition have been reported by Laënnec,[33] Albers,[34] Bromann,[35] Kilian,[36] Küster,[37] Enzmann,[9] von Winiwarter,[38] Weichselbaum,[39] von Recklinghausen,[40] Bostroem,[41] Rokitansky,[42] Fitz,[43] Tillaux,[44] and Ramonet.[45]

Pigment Deposits.—In chronic obstructive jaundice the contents of the duct may become golden-brown to green in color, due to the presence of the bile constituents, and the walls of the duct may become deeply tinged also.

Progressive Changes.—Inflammations about the duct often cause secondary changes in the wall of the duct, producing localized or general thickenings, which may become so marked that the lumen is markedly occluded.

Heller[3] reported such a case in a woman, aged fifty-six, who had marked œdema of the pelvic tissues accompanied by ascites. At autopsy he found that the wall of the thoracic duct was greatly thickened throughout, and that its lumen was almost completely obliterated. He explained this thickening as inflammatory. Andrals[7] reported a similar localized finding. In his case the lumen of the duct was greatly reduced by a localized increase of scar tissue at the level of the fifth dorsal vertebra.

In cases of puerperal sepsis or general septicæmia in which the abdominal lymph vessels contain pus, or the mesenteric glands are the seats of secondary abscesses, the thoracic duct may become involved. In such cases its walls become swollen, due to congestion, œdema, and infiltration with leucocytes, and its lumen may contain pus. In these cases general pyæmia, if not already present, usually results.

Cases in which pus has been found at autopsy in the thoracic ducts have been seen by Adams,[5] Worms,[6] Andrals,[7] Gendrin,[8] Enzmann,[9] and Schweininger.[10]

Tuberculosis.—When it is considered how often the bronchial or mesenteric lymph glands are affected with tuberculosis, it seems strange that more cases are not reported in which the thoracic duct is involved secondarily, on the one hand through its close proximity, and on the other through its direct communication with the seat of infection. That the condition is not so rare as the few reported cases would indicate is shown by Stilling, who found tubercles in the thoracic duct of five in a series of eighteen cases of general miliary tuberculosis.

Cooper[11] in 1798 was the first to observe tuberculosis of the duct. His case was one of general tuberculosis, and at autopsy he found several caseous masses behind some of the valves of the duct. Ponfick,[12] in 1877, pointed out the significant fact that many cases of general miliary tuberculosis were due to a secondary involvement of the duct from tuberculous bronchial lymph glands, with subsequent dissemination of the tubercle bacilli through its stream into that of the blood. He was able to demonstrate this fact in a case which he reported, and drew the conclusion that it was possible in many cases to trace the sudden generalization of tuberculosis to a similar source. Since the report of his case, Benda[13] and Stilling[14] have made similar observations, and have confirmed the conclusions drawn by Ponfick.

In some cases the lumen may become markedly obstructed and the walls of the duct greatly thinned, owing to the presence of large caseous masses blocking the lumen. In other cases only scattered tubercles are present, either behind a valve flap or between two valves. These scattered tubercles are for the most part small semitransparent grayish nodules varying in size from a pin point to a pinhead. Sometimes many of these tubercles coalesce and form a mass, slightly elevated above the surface, about the size of a split pea. The tubercles are closely adherent to the intima, and when pulled off leave a depressed bleeding ulcer with edges slightly undermined. If the bacilli lodge behind a valve flap, tubercles form which rapidly caseate and coalesce, forming a semi-solid grayish-yellow mass which pushes the valve out into the lumen and sooner or later causes obstruction to the flow in the lumen.

Besides the observers mentioned, Talma,[15] Nasse,[18] Poney,[19] Cruikshank,[20] Hopfgärtner,[21] Lientaud,[22] Otto,[61] Weigert,[23] Brash,[65] Schurhoff,[63] and Whitla[64] have reported cases of tuberculosis of the thoracic duct.

Tumors.—As yet no cases of the mature connective-tissue tumors in the walls of the thoracic duct have been reported.

Sarcoma.—A few instances of this class of tumors have been reported. Rust,[62] in 1815, was the first to observe a sarcoma in the thoracic duct. Otto,[61] in 1824, saw another case. Both cases were secondary to a sarcoma in the testis. The third case in the literature was reported by Winkler[28] in 1898. His patient was a young man, twenty years old, who had a mediastinal tumor. At autopsy Winkler found that the wall of the duct was irregularly thickened, and in areas he found distinct secondary nodules. Microscopically the mediastinal tumor and its secondaries were found to be round-cell sarcomata. One case of metastatic sarcoma of the duct has been seen at the Pathological Laboratory of the University of Michigan. The primary was a malignant teratoma of the testis which had given rise to a secondary sarcoma in the receptaculum chyli, about the size of an English walnut. The lumen was completely occluded.

Carcinoma.—Although carcinomata of the abdominal and pelvic organs frequently give rise to secondaries in the thoracic organs, it is not common to find the thoracic duct involved by secondary growths. This may be due, partly, to the fact that the thoracic duct has but few valves, and these are rudimentary, so that cancer cells do not lodge readily; but it must be admitted that this is a very insufficient reason. In 1898 Winkler[28] collected all the cases of carcinoma of the thoracic duct, which had been previously reported. He found fifteen in all, and added eleven more of his own; but from his study of these cases he drew no definite conclusion as to this infrequent involvement of the thoracic duct, unless it be that this organ is seldom examined at autopsy, and then often very superficially.

Of the 26 cases of secondary carcinoma of the duct 10 were primary in the stomach (Acker,[24] Leydecker,[1] Hektoen,[25] Barybuhr,[26] Pannenburg,[27] Winkler[28]); 8 in the uterus (Andral,[7] Winkler,[28] Enzmann,[9] Unger[29]); 3 in the gall-bladder (Behrens,[30] Winkler[28]); 1 in the testis (Cooper[11]); 1 in the pharynx (Virchow[31]); 1 in the ovary (Senator[32]); 1 in the right adrenal (Winkler[28]), and 1 in the kidney (Winkler[28]). In all cases secondary growths were present in the retroperitoneal lymph glands. Some authors mentioned secondary nodules in the lungs or cervical lymph glands, but they were not common.

The nodules in the duct may be small and not easily outlined, or they may be so large that they partially or wholly close the lumen of the duct. In such cases dilatation occurs behind the obstruction, and unless the anastomoses can cope with the lymph thus held back, chylo-thorax, chylous ascites, or both, may result, depending upon the grade of obstruction and the location of the tumor masses.

Parasites (see article on *Parasites*).—Of the parasites found in man, cases have been reported in which cysticerci and filaria have been found in the lumen of the thoracic duct.

Rupture.—Traumatism of the thoracic duct, resulting in rupture, may be due to an injury of the thorax, or may be caused during an operation in the lower left cervical region. Traumata of the first sort are not common because of the protected position of the duct; nevertheless in severe injuries of the thorax and abdomen or as the result of severe straining, such as severe coughing, rupture of the duct may occur. Manley[49] reported a case of rupture of the duct in a young man who had received a severe blow over the abdomen, followed by symptoms of peritonitis, accompanied by a fluctuating, non-reddened swelling in the right iliac fossa, which contained chyle. This sac was drained for fifteen days and healed. Manley thought that the duct had been ruptured, but since he did not open the peritoneal cavity other than to drain the sac, it cannot be positively stated that his diagnosis was correct.

The first authentic case of rupture of the duct was one cited by Monroe[50] in 1765. The patient had had chylous ascites, and at autopsy he found a rupture of the duct at the level of the fourth dorsal vertebra. Kirchner[51] was able to find only seventeen cases in the literature in which the rupture resulted directly from trauma. To these he added another of what he considered a traumatic rupture. The patient was a child, nine years old, who had fallen against a window sill, injuring the thorax. In ten days this was followed by marked dyspnoea and ascites. Aspiration showed the presence of chyle in the abdomen. These symptoms persisted for ten days and then gradually disappeared.

Since then Eyer,[52] Port,[53] and Lyne[54] have reported cases in which there could be little doubt that the duct was ruptured, since chylous ascites and chylothorax were present in every case.

Rupture of the duct may occur during operations for the removal of sarcomatous, carcinomatous, or tuberculous lymph glands of the left lower cervical region, but that this is not a common occurrence is shown by the few cases reported and by a series of thirty-five cases cited by Cushing in which the lymph glands of this region contained secondary new growths. Rupture of the duct during their removal occurred in only two cases.

The rupture may be noticed at the time of the operation, or it may escape observation altogether until the wound is subsequently dressed. If noticed at the time of the operation, the rupture is usually recognized by a sudden gush of milky fluid. Sometimes it may be a serous fluid. If not noticed at the time of rupture, it may be recognized by the presence of a milky or opalescent fluid in the wound or on the dressings at a subsequent visit.

These ruptures are not usually fatal, although a large amount of the contents of the duct may be lost. Paton,[56] on the other hand, reported a case of rupture in which 1,584, 3,168, and 4,752 c.c. of chyle were lost on three consecutive days; death followed soon afterward. Thöle[55] in 1900 was able to find in the literature fifteen cases of rupture of the duct during operation and added a personal case. Besides those collected by them, Paton,[55] Schoff,[57] Allen and Briggs,[58] Weischer,[59] and Cushing[60] have reported cases.

Most of these surgeons either pack the wound tightly or ligate the duct, and the rupture then heals.

THORAX.—The thorax is that part of the great body cavity which is situated above the diaphragm. It contains the organs of respiration and circulation, together with many large vessels and nerves. It is in shape the form of a truncated cone with the base directed downward and formed by the diaphragm, and the truncated apex continuous with the root of the neck. Superficially the thorax presents an anterior wall, two lateral walls, and a posterior surface. The anterior thoracic wall is separated above from the anterior surface of the neck by the prominent ridge of the clavicle, joining the upper and outer angle of the first piece of the sternum to form the prominent sterno-clavicular articulation. Between the inner extremities of the two clavicles and above the upper border of the sternum, we find the deep suprasternal notch. Running downward in the median line to the tip of the ensiform cartilage is the midsternal line, which in the living subject is indicated by a furrow between the sternal attachments of the pectoralis major muscle on each side. Along the outer border of the sternum is the sternal line. At the junction of the first and second pieces of the sternum is a transverse ridge known as Ludwig's angle, which marks the attachment of the second costal cartilage to the sternum. As the first rib is not palpable, on account of its position behind the clavicle, Ludwig's landmark is commonly used in counting the ribs on the living subject. Extending vertically through the nipples on each side is the mammillary line. Half-way between the sternal line and the mammillary line and parallel to them is the parasternal line. The anterior axillary line is drawn vertically downward from the point where the anterior axillary fold, or the lower border of the pectoralis major, joins the chest wall. The posterior axillary line is drawn from the posterior axillary fold, which is formed by the latissimus dorsi. Midway between these two lines and extending downward from the highest point or apex of the axilla is the midaxillary line. The surface markings on the posterior surface of the thorax are few. In the median line we have the furrow lying over the tips of the spinous processes. The scapular line is drawn vertically downward from the inferior angle of the scapula. The spine of the scapula, running upward and outward to terminate in the acromion process, is easily felt. The inferior boundary of the thorax is formed by the costal cartilages of the lower ribs from the seventh to the tenth inclusive. These, with the ensiform cartilage, form the costal arch, which separates the anterior thoracic surface from the anterior surface of the abdomen.

The thorax has two openings, a superior and an inferior. The superior opening of the thorax is much the smaller, measuring in antero-posterior diameter about 2¼ inches (5.7 cm.). It is bounded in front by the upper border of the manubrium and the first costal cartilage; laterally by the shaft of the first rib; behind, by the body of the first dorsal vertebra and the head of the first rib. Passing through it we have the following structures: sterno-hyoid, sterno-thyroid, and longus colli muscles; the innominate, left common carotid, left subclavian, superior intercostal, and internal mammary arteries; the right and left innominate veins; the right and left phrenic and pneumogastric nerves and the left recurrent laryngeal and the right and left gangliated cords of the sympathetic, and the cervical cardiac branches of the pneumogastric; the œsophagus, trachea, and thoracic duct, with the apices of the lungs invested in pleura.

The inferior opening is bounded in front by the ensiform cartilage and the common cartilage of the lower ribs, laterally, by the eleventh and twelfth ribs, and posteriorly by the body of the last dorsal vertebra. The opening is closed by the diaphragm, which separates the thoracic cavity above from the abdominal cavity below. It is pierced by a number of structures: through the aortic opening, between the two crura of the diaphragm, pass the aorta, thoracic duct, and vena azygos major; through the œsophageal opening, the œsophagus, right and left pneumogastric nerves, and the œsophageal branches of the thoracic aorta; on the right side, through an opening of its own, the inferior vena cava; while the greater, lesser, and least splanchnics and the continuation of the thoracic gangliated cord perforate the crus on each side, and on the right side alone the phrenic nerve pierces the right leaflet of the diaphragm anteriorly and a little externally to the opening for the inferior vena cava.

The walls of the thorax are formed anteriorly by the sternum and the costal cartilage, laterally by the shafts of the ribs, and posteriorly by the bodies of the twelve dorsal vertebræ and the heads and necks of the ribs. On transverse cross section, the thorax presents a reniform outline, the deep notch at the back being formed by the intrusion of the bodies of the dorsal vertebræ into the thoracic space. The various diameters of the chest at different levels are given by Holden as follows: In the average skeleton the antero-posterior diameter at the inlet is 2¼ inches (5.7 cm.); at the outlet, 5⅝ inches (14.25 cm.); while at the junction of the manubrium and gladiolus the antero-posterior diameter is 4½ inches (11.2 cm.). The inlet measures in transverse diameter 4⅜ inches (11 cm.); it gradually increases as far as the ninth rib, where the transverse diameter measures 10½ inches (26.6 cm.). From the ninth to the twelfth rib this diameter decreases. The female thorax has a smaller capacity than the male, the sternum is shorter, the ribs are more movable, and the difference between the upper and the lower openings is less. Abnormal forms are frequently found in which the relation between the different diameters that exist in the normal thorax is disturbed. A pigeon chest is one in which the sternum and costal cartilages project forward, the antero-posterior diameter being longer and the transverse diameter shorter than normal. It is usually found as one of the results of rickets. The barrel chest is one in which the antero-posterior and transverse diameters are nearly equal and the costal angle is an obtuse angle. It is frequently found in emphysema. The flat chest is one with a long transverse diameter and a short antero-posterior diameter. The costal angle in these cases is acute.

The spaces between the ribs are called the intercostal spaces and are closed by the external and internal intercostal muscles. The external intercostals are eleven in number on each side. They begin behind at the tubercles of the ribs and arise from the lower border of each rib as far forward as the ends of the ribs in front. Their fibres pass downward and forward and are inserted into the upper border of the rib below. The internal intercostals take their origin from the ridge on the inner surface of each rib, and the under border of the costal cartilages from the sternum as far back as the angles of the ribs. Their fibres pass downward and backward, at an acute angle to those of the external intercostal, and are inserted in the upper border of the rib below. By means of the ribs and the intercostal spaces many important structures in the thorax are located. The fourth interspace is identified in the male by the nipple. The lower border of the pectoralis major muscle marks the course of the fifth rib. The apex beat of the heart is found in the left fifth interspace one inch and a half below the nipple, and three-quarters of an inch toward the median line. The surface markings for the heart, as given by Deaver, are as follows: Take a point on the third right costal cartilage half an inch from the border of the sternum; from it draw a line to a point in the second interspace on the left side of the sternum, one inch from the left sternal margin. This line will indicate the base of the heart. From a point in the fifth interspace, one inch to the inner side of and two inches below the nipple, draw a line to a point half an inch to the right of the sternum in the fifth interspace. This line will locate the lower border of the heart. Connect the two extremities of the two lines as drawn and the included quadrangle will represent the heart area. A point just behind the sternal end of the third left intercostal space will indicate the position of the aortic valve; behind the third left chondrosternal articulation are the pulmonary valves. The tricuspid valve is found in the median line on the level of the fourth intercostal space; the mitral, at the left border of the sternum behind the fourth left costal cartilage.

Contents of the Thorax.—*Pericardium.*—The pericardium is a fibroserous sac composed of two layers: an outer or fibrous, and an inner or serous. The outer or fibrous layer is continuous above with the fibrous sheath of the great vessels and ultimately blends with a layer of deep cervical fascia, which passes behind the sterno-cleido-mastoid muscle, forming a sheath in the neck for the carotid artery, internal jugular vein, and pneumogastric nerve. It is continuous below with the upper layer of the fibrous covering of the diaphragm. It is attached in front to the under surface of the sternum by the superior and inferior sterno-pericardiac ligaments. The serous portion of the pericardium, like all serous membranes, consists of two layers—a parietal and a visceral. The parietal layer lines the inner surface of the fibrous portion and forms the wall of the pericardial cavity. The visceral layer covers the heart muscle and lies in intimate contact with it. The two layers are continuous with each other at the roots of the great vessels and form a closed cavity, which contains a small amount of serous fluid, for the purpose of lubrication. When from an increase of pericardial fluid this sac becomes distended abnormally, the pericardial area can be outlined on the chest wall, and can be distinguished from the dulness due to cardiac hypertrophy by the fact that the area of pericardial dulness has its apex upward and to the right and its base downward, while an hypertrophied heart has its apex directed downward and to the left and its base upward and to the right.

If on the dissecting table, or at a post-mortem examination, the pericardium be incised in the median line and a transverse incision made at right angles to the first cut, the pericardium can be reflected in four V-shaped flaps, and the anterior surface of the heart inspected in its normal condition. The surface of the heart which presents itself will be almost entirely right ventricle, while the apex of the right auricle can be seen at the upper right border of the heart. If now the apex of the heart be drawn upward and slightly to the left, the pericardial cavity can be seen and inspected. Running from the lower right-hand corner of the pericardial space upward to the heart is the large inferior vena cava. If this be cut and continued traction made upon the heart, the right and left inferior pulmonary veins will next be seen. Above these the pulmonary arteries and the right and left superior pulmonary veins are found. It is not the purpose of this article to go into a detailed description of the structure of the heart, which will be found in a separate article under an appropriate heading. (See *Heart.*)

The Pleura.—The pleura consists of two closed serous sacs which invest the lungs and line the thoracic cavity. Each pleura consists of two layers, a parietal, which lines the internal surface of the thoracic wall, and a visceral, which is closely adherent to the surface of the lungs. The pleura extends into the neck for a distance of an inch and a half to two inches above the upper border of the first rib, where it forms a closed sac which receives the apex of the lung. Inferiorly it covers the upper surface of the diaphragm and extends down in front to the costal cartilage of the seventh rib, on the left side to the lower border of the tenth rib, and on the right to the upper border of the tenth rib; behind, it passes to the upper border of the twelfth rib, or may pass as low as the lower border of the twelfth or the transverse process of the first lumbar vertebra. The two pleuræ are not connected at any point, but touch, or may even overlap, on a level with the junction of the first and second pieces of the sternum, the left usually overlapping and lying anterior to the right. At the fourth costal cartilage the two sacs diverge, the right running almost straight downward to the ensiform cartilage, from which point it passes behind the seventh costal cartilage to the diaphragm. The left sac passes outward, downward, and to the left from the fourth costal cartilage to the left margin of the sternum, on a level with the fifth costal cartilage, from which point it passes downward and outward on the under surface of the seventh costal cartilage. The inferior lateral limits of the pleural sacs have been already described. On transverse section of the thorax the relations of the pleuræ to each other, as well as the continuity between the parietal and visceral layers, can be demonstrated. Beginning at the median line in front, the anterior parietal pleura lies on the posterior surface of the sternum, passing thence to the posterior surface of the costal cartilages and intercostal muscles, follows the curve of the costal wall and becomes the lateral parietal pleura. Following the curves of the ribs it passes to the posterior wall of the thorax, and, as posterior parietal pleura, passes to the sides of the bodies of the dorsal vertebræ. On the left side it now passes over the abdominal aorta and the left thoracic gangliated cord, while on the right side it covers over, at different levels, the superior vena cava, the inferior vena cava, vena azygos major, and right thoracic gangliated cord. It next passes to the posterior surface of the root of the lung, and thence to the posterior surface of the lung itself, becoming the posterior visceral pleura, or, as it is sometimes called, the pleura pulmonalis. It now invests the lung, covering posterior, lateral, and anterior surfaces in order, as far as the anterior border of the lung, and passing as a septum into the fissures which separate the lobes of the lung. From the anterior border of the lung it passes on to the internal surface of the lung as far backward as the anterior surface of the root of the lung, which it next covers. From this point it passes on to the external surface of the pericardium and forward to the starting-point, becoming again the parietal pleura.

The Lungs.—The lungs are the organs of respiration, and are placed one on each side of the chest, separated by the mediastinum and its contents. Each lung is conical in shape and has an apex, a base, an internal and an external surface, and an anterior and a posterior border. The apex projects into the neck for about an inch and a half above the upper border of the clavicle, and lies in the conical cavity formed by the apex of the pleura. The base is concave, to conform with the convex upper surface of the diaphragm. Its lower border is marked by a line drawn from the articulation of the sixth costal cartilage with the sixth rib to the spinous process of the tenth dorsal vertebra. Owing to the presence of the liver the right lung lies higher in the chest than the left, being on a level in front with the upper border of the fifth costal cartilage, while the lower border of the left passes down to the upper border of the sixth rib. The outer surface of the lung, or the thoracic surface, is smooth, convex, and conforms to the curve of the thoracic wall except in the portion which extends up into the neck. It is sometimes divided into an anterior, a lateral, and a posterior thoracic surface. The inner surface is deeply concave, owing to the position of the heart and pericardium. It is separated from the external surface, in front by the sharp anterior border, and behind from the posterior surface by the root of the lung. The anterior border is thin, sharp, and separates the external and internal surfaces. It overlaps the pericardium and follows closely the anterior internal border of the pleural sacs, as described above, except that the edges of the lungs do not overlap. The anterior border of the right lung reaches to the median line, while the left reaches to the left border of the sternum. The posterior border is round and broad, and lies in the concavity formed by the angle of the ribs on either side of the spinal column. It is much longer than the anterior border and becomes wide as it passes downward.

The roots of the lung are formed by the bronchi, the pulmonary arteries and veins, the bronchial arteries and veins, and the pulmonary nerves and lymphatics. These structures lie in the following order: from before backward, the pulmonary veins, pulmonary artery, and the bronchus; from above downward on the right side, the bronchus, the pulmonary artery, and the pulmonary veins; on the left side, the pulmonary artery, the bronchus, and the pulmonary veins, the bronchus lying above on the right side and in the middle on the left side.

Lobes.—Each lung is divided into an upper and a lower lobe. The division is about three inches below the apex. On the right side the upper lobe is again subdivided into two lobes by a horizontal fissure which passes forward from the middle of the first fissure to the anterior border of the lung. The right lung is also larger and heavier than the left, but its transverse diameter is greater than that of the left lung and its vertical diameter shorter. The left lung is longer than the right, but is much narrower.

Mediastinum.—The mediastinum is that portion of the thoracic cavity which is not contained within the pleural sacs. It is an irregularly shaped space bounded below by the diaphragm, in front by the sternum and costal cartilages, behind by the vertebral column, and extending above into the neck as far as the apices of the pleuræ. It is consequently limited above by the deep cervical fascia and the structures which pass through the superior opening of the thorax. It is divided, in a purely arbitrary manner, by a plane which passes through the junction of the manubrium and gladiolus in front, and the lower border of the body of the fourth dorsal vertebra behind. This plane corresponds with the upper border of the pericardium. The portion of the mediastinum above this plane is called the superior mediastinum. It is bounded in front by the posterior surface of the manubrium and the first and second costal cartilages, behind by the anterior surfaces of the bodies of the upper four dorsal vertebræ. Its lateral boundaries are the right and left pleural sacs. It contains the transverse portion of the arch of the aorta, the innominate artery, the left common carotid and subclavian arteries, and the superior intercostal artery; the right and left innominate veins, and the superior vena cava; the pneumogastric, the phrenic and cervical cardiac and left recurrent laryngeal nerves, and the upper portion of the thoracic gangliated cords on each side; the origins of the sterno-hyoid and sterno-thyroid muscles and a portion of the longus colli, the trachea, œsophagus, and thoracic duct. The inferior mediastinum is subdivided by the pericardium into three portions—the anterior, which lies in front of the pericaridum; the middle, which lies within the pericardium; and the posterior, which lies behind the pericardium. The anterior mediastinum is bounded in front by the posterior surface of the lower part of the sternum; behind, by the anterior surface of the fibrous layer of the pericardium; and below, by the attachment of the diaphragm to the ensiform and costal cartilages. It contains fat, areolar tissue, and a few lymphatic glands, which drain the inner and lower quadrant of the mammary gland. The middle mediastinum is bounded by the limits of the pericardium. It contains the heart and the roots of the great vessels. The posterior mediastinum comprises all the space bounded in front by the posterior layer of the pericardium, behind by the bodies of the lower eight dorsal vertebræ and the heads and necks of the ribs, above by the supposititious plane separating it from the superior mediastinum, and below by the upper surface of the diaphragm. It contains the following structures: the descending portion of the thoracic aorta and its branches, viz., the lower intercostal arteries, the œsophageal, bronchial, pericardiac, and posterior mediastinal branches, and the corresponding veins; the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the œsophagus, thoracic duct, and the posterior mediastinal lymphatics.

The Aorta.—The thoracic aorta is divided into three portions—the ascending portion, the transverse portion or arch, and the descending portion. The ascending aorta is about two inches long; commencing at the upper part of the left ventricle, it passes obliquely upward, forward, and to the right as far as the upper border of the second right costal cartilage, where it becomes the transverse aorta. At its commencement it is somewhat distended, and opposite the three cusps of the aortic valve presents three small dilatations, called the sinuses of Valsalva. These sinuses are placed one in front and two behind. From the anterior sinus is given off the right coronary artery, and from the left posterior sinus the left coronary artery.

The transverse aorta, beginning at the upper border of the second right costal cartilage, passes upward, backward, and to the left, lying on the anterior surface of the body of the fourth dorsal vertebra. It then curves downward and backward to the lower border of the fourth dorsal vertebra on the left side, where it becomes the descending aorta. The branches given off from the transverse portion of the aorta are the innominate and the left common carotid and subclavian. The innominate artery, or brachiocephalic, arises from the beginning of the arch of the aorta on a level with the upper border of the second right costal cartilage, and passing upward, forward, and to the right, divides behind the right sternoclavicular articulation into the right common carotid and subclavian arteries. It varies in length from one to two inches. The innominate usually gives off no other branches, but occasionally the thyroidea ima, which ascends in front of the trachea and supplies the lower portion of the thyroid gland, is found arising from it. The left common carotid arises from the left portion of the arch of the aorta, between the innominate and the left subclavian. It passes upward, outward, and to the left, behind the left sterno-clavicular articulation, and, ascending into the neck, divides into the internal and external carotid arteries, on a level with the upper border of the thyroid cartilage.

The left subclavian artery arises from the arch of the aorta behind and to the left of the left common carotid, and passes nearly vertically upward to the inner border of the scalenus anticus muscle. It then curves outward, lying behind the scalenus anticus muscle, forming the second portion of the artery, and separated by the muscle from the subclavian vein which lies in front.

The descending aorta begins at the lower border of the fourth dorsal vertebra on the left side, and passes downward and slightly to the right, curving to conform to the spine on which it rests and whose curves it follows. It lies in the back portion of the posterior mediastinum and gives off the following branches: pericardiac branches to the pericardium; bronchial branches to the substance of the lungs, usually a single one on the right side, and two on the left. The bronchial arteries pass along the posterior surface of each bronchus, and, following the course and division of the bronchial tubes, supply the bronchia, the substance of the lungs, and the retro-bronchial glands. The œsophageal arteries, varying in number from three to five, arise from the anterior surface of the aorta and pass downward on the œsophagus, which they supply, anastomosing with the branches of the inferior thyroid above and with the œsophageal branches of the gastric arteries from the cœliac axis of the abdominal aorta below. The posterior mediastinal arteries are a number of branches given off by the thoracic aorta, which supply the glands of the posterior mediastinum. The intercostal arteries arise in pairs from the posterior surface of the descending aorta. There are usually nine on each side. The two upper intercostal spaces receive their blood supply from the superior intercostal branch of the subclavian and from the anastomosis between this artery and the first aortic intercostal. The right intercostal arteries are longer than the left, as they have to pass across the spinal column to reach the right intercostal spaces. The arteries lie first between the pleura and the external intercostals; then, at the angles of the ribs, they pass between the external and internal intercostal muscles; in each intercostal space the artery passes upward to the lower border of the rib above, where it lies between the vein above and the nerve below, except in the upper intercostal spaces, where the nerve at first lies above the artery. Passing forward as far as the anterior axillary line it anastomoses with the terminal branches of the anterior intercostals from the internal mammary artery. This description applies to the upper six intercostal spaces. In the seventh, eighth, and ninth spaces the artery anastomoses with the intercostal branches of the musculo-phrenic artery, while the two lower intercostal arteries, running along the lower border of the eleventh and twelfth ribs, pass forward and downward to the muscles of the abdominal wall.

The pulmonary artery arises from the apex of the right ventricle in front of the aorta and passing upward divides into two branches, the right and left pulmonary arteries. The right pulmonary artery is longer than the left and passes outward and backward behind the ascending aorta and the superior vena cava to the root of the right lung, where it divides into branches; a large branch going to the upper lobe and a smaller branch to the lower lobe. The large upper branch gives off a branch to the middle lobe. The left pulmonary artery passes outward in front of the descending portion of the aorta to the root of the left lung where it divides into two branches, which are distributed to the upper and lower lobes. The relation of the structures in the root of the lung has already been noted.

The superior intercostal artery is a branch of the subclavian, arising from the upper and back portion of the artery, and passing downward and backward behind the pleura in front of the necks of the first two ribs. It supplies the first intercostal space and anastomoses with the first aortic intercostal to supply the second. The internal mammary artery arises from the subclavian from the under surface of the first portion of the artery. It passes directly downward behind the first costal cartilage to the inner surface of the anterior thoracic wall, lying on the costal cartilages about half an inch from the border of the sternum. In the sixth intercostal space it divides into its two terminal branches, the musculo-phrenic and superior epigastric. It gives off in its course a number of small branches which supply the anterior thoracic wall and mediastinal structures. The comes nervi phrenici or the superior phrenic artery joins the phrenic nerve and accompanies it to the diaphragm, where it anastomoses with the phrenic arteries from the internal mammary and abdominal aorta. The mediastinal arteries are small branches, six to eight in number, which are distributed to the lymphatic glands of the anterior mediastinum. The pericardial branches supply the anterior surface of the pericardium. The sternal branches supply the triangularis sterni muscle and the posterior surface of the gladiolus. The anterior intercostal arteries pass outward in the intercostal spaces and anastomose with the terminal branches of the aortic intercostals. They lie first between the pleura and the internal intercostal muscles and then between the internal and external intercostals. The perforating or mammary branches arise from the internal mammary artery in the upper five intercostal spaces. Piercing the intercostal muscle they pass directly forward and outward and supply the pectoralis major muscle and the under surface of the inner half of the mammary gland. In the male these arteries are small and comparatively unimportant, but in the female, especially during pregnancy and lactation, they are of large size. The musculo-phrenic artery, a terminal branch of the internal mammary, passes downward and outward from the sixth intercostal space behind the costal cartilages and terminates opposite the last intercostal space. It gives off the lower anterior intercostal arteries and branches to the costal margin of the diaphragm and to the portion of the abdominal wall which lies immediately below the costal arch. The superior epigastric artery is the continuation in line of the internal mammary artery. It passes between the costal and sternal attachments of the diaphragm, and, penetrating behind the rectus abdominis muscle, supplies it; at the same time it anastomoses with the deep epigastric from the external iliac, forming a deep circle of anastomosis in the substance of the abdominal wall, between the subclavian artery above and the femoral artery below.

The internal mammary artery is sometimes wounded in stab or gunshot wounds. It can be reached and tied by an incision in the centre of any of the upper six intercostal spaces, parallel to the costal cartilages, and the artery ligated about half an inch external to the outer border of the sternum.

Veins.—*Inferior Vena Cava.*—The inferior vena cava is formed at the lower border of the fourth lumbar vertebra by the junction of the right and left common iliac veins. It passes upward on the right side of the vertebral column, receiving tributaries from all of the pelvic and abdominal viscera except the organs of digestion. It perforates the central tendon of the diaphragm on the right of the median line, and, entering the pericardium, where it is covered by the serous layer, it terminates in the lower and posterior portion of the right auricle. The portion of the inferior vena cava lying in the thorax is short, and is best seen, after incision of the pericardium, by drawing the apex of the heart upward and to the left.

Innominate Veins.—The right and left innominate veins are formed by the junction of the subclavian and internal jugular veins on each side, just behind the sterno-clavicular articulation. The left is much longer than the right, being about two and a half inches in length, and passing from the left sterno-clavicular articulation downward and to the right to the junction of the first costal cartilage with the right border of the sternum, where it joins the right innominate vein to form the superior vena cava. The right is shorter and smaller and passes from the right sterno-clavicular articulation almost directly downward to its junction with the left. The tributaries of the right innominate vein are the right vertebral, internal mammary, inferior thyroid, and superior intercostal veins. Those of the left are the corresponding veins on the left side of the body with occasionally some veins from the thymus gland and the pericardium.

Superior Vena Cava.—The superior vena cava, formed by the junction of the right and left innominate, passes vertically downward and, piercing the pericardium, enters the upper part of the right auricle on a level with the upper border of the third right costal cartilage.

Azygos System.—The azygos veins serve to connect the superior and inferior venæ cavæ. They are three in number. The right azygos vein, or vena azygos major, is formed in the abdomen by branches of the lumbar veins, enters the thorax through the aortic opening in the diaphragm and passes up through the posterior mediastinum, lying on the right side of the vertebral column. At the upper border of the fourth dorsal vertebra it passes forward over the root of the right lung, receives the right bronchial vein, and empties into the superior vena cava at the point where the latter pierces the pericardium. It has as tributaries the right superior intercostal vein, the intercostal veins of the right side, the vena azygos minor, the right bronchial vein, and a portion of the veins from the œsophagus. The left, or vena azygos minor, is formed by a branch from one of the lumbar veins, or by a tributary from the left renal. Entering the thorax through the left crus of the diaphragm it passes up on the left side of the vertebral column as high as the ninth dorsal vertebra, where it curves to the right across the vertebral column behind the aorta and thoracic duct and empties into the right azygos vein. Its tributaries are the lower intercostal veins on the left side and the mediastinal and œsophageal branches. The left upper azygos vein, sometimes called the azygos tertia, or superior azygos, is not always present. When found it varies inversely in size with the left superior intercostal vein. It drains the upper left intercostal spaces and empties into the azygos major above its junction with the minor. When this vein is absent the space usually occupied by it is drained by the left superior intercostal vein. The internal mammary vein accompanies the artery and has tributaries corresponding to the branches given off by the artery. It is frequently found to be double, forming venæ comites lying on each side of the artery and connected at short intervals by cross branches. When the artery is tied care should be taken in passing the needle not to include the veins in the ligature. The two veins when present unite to form a single trunk, which empties into the innominate vein on either side.

Nerves.—The pneumogastric, or tenth cranial nerve, enters the thorax between the subclavian vein and artery, lying on the right side just behind the junction of the internal jugular and subclavian, and on the left side between the left carotid and subclavian arteries. Owing to the obliquity of the arch of the aorta the relations of the nerve on the two sides differ. On the right side it descends along the side of the trachea to the posterior portion of the root of the lung, where it gives off the posterior pulmonary branches which spread out to form a plexus, from which two cords descend on the œsophagus, breaking up into a network of branches, which, uniting with similar branches from the nerve on the opposite side, form the œsophageal plexus. Lower down on the œsophagus the fibres again unite to form a single cord which, running along the posterior surface of the œsophagus, passes with it through the œsophageal opening in the diaphragm and is distributed to the posterior surface and greater curvature of the stomach, communicating with the solar, splenic, and cœliac plexuses. The left pneumogastric nerve crosses in front of the arch of the aorta, giving off at this point the left recurrent laryngeal, which, winding around the arch of the aorta from before backward, passes upward in the groove between the œsophagus and trachea and enters the larynx, being distributed to all the muscles of the left side of the larynx except the crico-thyroid. As the recurrent laryngeal nerve on the right side comes off behind the sterno-clavicular articulation and winds around the first portion of the subclavian, and supplies the muscles of phonation on the right side of the larynx, an aneurism of the first portion of the right subclavian would cause pressure paralysis of the right vocal cord, while an aneurism situated in the arch of the aorta would cause a paralysis of the left vocal cord. The left pneumogastric nerve passes behind the root of the left lung, gives off the posterior pulmonary branches to the pulmonary plexus, as described, and the main portion of the nerve, descending along the anterior surface of the œsophagus, passes through the œsophageal opening in the diaphragm and is distributed to the anterior surface and lesser curvature of the stomach, joining branches from the hepatic plexus. The only other thoracic branch of the pneumogastric nerve besides those mentioned is the anterior pulmonary nerve, which passes in front of the root of the lung, and, joining filaments from the sympathetic, forms the anterior pulmonary plexus.

Phrenic Nerve.—The phrenic nerve arises from the third, fourth, and fifth cervical, passes diagonally downward and outward across the anterior surface of the scalenus anticus muscle, and then, continuing its course between the subclavian artery and subclavian vein, enters the thorax, lying on the right side just external to the superior vena cava and on the left side external and anterior to the subclavian artery. Passing in front of the root of the lung, it lies between the pleura and the pericardium, to both of which it gives off branches. It is longer on the left side than on the right, on account of the oblique position of the heart and because the left nerve forms a loop in passing around the left side of the pericardium. On the right side it breaks up into from three to seven branches about 1 cm. above the upper surface of the diaphragm. These branches, piercing the diaphragm, supply it, while the innermost branch passes down to communicate with the right semilunar ganglion of the solar plexus. On the left side the nerve does not perforate the diaphragm, but ramifies in its substance.

Intercostal Nerves.—The intercostal nerves, twelve in number, are derived from the anterior division of the dorsal nerves. The anterior division of the first dorsal nerve divides into two branches, the larger of which joins the eighth cervical to form the lower trunk of the brachial plexus. The smaller branch forms the first intercostal nerve. The anterior divisions of the second, third, fourth, and fifth dorsal nerves form the intercostal nerves for the respective intercostal spaces. They pass forward between the pleura and the external intercostal muscles, as far as the angle of the ribs, where they pass between the external and internal intercostal muscles as far as the middle of the shaft. Here they enter the substance of the internal intercostals and run through their substance as far as the costal cartilages, where they lie between the internal intercostal and the pleura. Breaking up into branches, they send cutaneous filaments to the front of the chest and the mammary gland, forming the anterior cutaneous nerves of the thorax. At the midaxillary line each one of the six upper intercostal nerves except the first gives off a lateral cutaneous branch which pierces the external intercostal and serratus magnus and divides into two branches, an anterior and a posterior. The anterior branch passes forward, supplying the anterior lateral surface of the chest and the skin over the external surface of the mammary gland. The posterior branches pass backward and supply the skin of the scapular region and over the latissimus dorsi. The lateral cutaneous branch of the second intercostal does not divide into two branches, but passes diagonally outward across the axilla, forming the intercostal humeral nerve, and, uniting with the nerve of Wrisberg, it supplies the skin of the inner and back portion of the arm above the elbow. This nerve is occasionally missing, or there may be two intercosto-humeral nerves, the second coming from the third intercostal.

The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves form the lower or abdominal intercostal nerves. They have the same relations in the intercostal spaces as the upper, but are distributed to the integument and muscles of the anterior abdominal wall, forming the anterior cutaneous nerve of the abdomen.

Sympathetic Nerves.—The thoracic gangliated cord is continuous above with the cervical gangliated cord, and enters the thorax on each side of the spinal column, lying along the heads of the ribs behind the great vessels covered over by the parietal pleura. The ganglia are twelve in number and are connected by nerve fibres forming cord like prolongations derived from the substance of the ganglia. The external branches from each ganglion communicate with the dorsal spinal nerves. The internal branches from the upper five ganglia enter into the formation of the posterior pulmonary plexus. The internal branches from the lower seven ganglia unite to form the three splanchnic nerves. They are called the greater, lesser, and least or renal splanchnic. The greater splanchnic is formed by the internal branches from the ganglia from the fifth to the tenth. These fibres unite to form a large nerve, which descends obliquely in front of the bodies of the lower dorsal vertebræ, pierces the crus of the diaphragm on each side, and terminates in the semilunar ganglion of the solar plexus, sending branches to the renal and suprarenal plexuses. The lesser splanchnic nerve is formed by the internal branches from the tenth and eleventh ganglia. It pierces the diaphragm and joins the solar plexus. The least or renal splanchnic arises from the twelfth ganglion, pierces the diaphragm, and joins the renal plexus.

The Œsophagus.—The œsophagus begins at the upper border of the cricoid cartilage, opposite the substance between the fifth and sixth cervical vertebræ, and enters the thorax in the median line lying between the vertebral column and the trachea. It passes downward and to the left in the posterior mediastinum, and, piercing the diaphragm to the left of the median line, expands into the stomach at the cardiac orifice. Its relations in the thorax are as follows: It lies behind the arch of the aorta, separated from it by the trachea. It passes downward and to the left, lying on the right of the aorta to a point just above the diaphragm, where it crosses to the left, passing in front of the artery and piercing the diaphragm. The pneumogastric nerves lie in close contact with it, the left lying in front and the right behind.

The Thoracic Duct.—The anatomical relations of the thoracic duct are described in the next article but one preceding this.

Trachea.—The trachea begins at the lower border of the cricoid cartilage and descends into the thorax, lying in front of the œsophagus, as far down as the upper border of the fifth dorsal vertebra, where it divides into the right and the left bronchus. The point of division is on a level with the junction between the first and second pieces of the sternum. The thoracic portion of the trachea therefore lies in the superior mediastinum. It has lying in front of it, besides the first piece of the sternum and the origins of the sterno-hyoid and sterno-thyroid muscles, which form the anterior thoracic wall at this point, the thymus gland, deep cervical fascia, and transverse aorta. On the left side lie the left common carotid artery, pneumogastric nerve, recurrent laryngeal nerve, and the pleura; on the right side, the innominate artery, right pneumogastric nerve, and pleura. The bronchi lie in the posterior mediastinum, entering into the formation of the roots of the lungs. The right bronchus is shorter and of larger size than the left, and passes more horizontally, the two bronchi diverging to form an angle of one hundred and thirty degrees. The left bronchus crosses in front of the œsophagus, the descending aorta and the thoracic duct, passes under the arch of the aorta, and enters the lung behind the pulmonary artery. The right bronchus passes horizontally to the right lung, passing above and then behind the pulmonary artery on that side. The relation of the structures that form the root of the lung has already been noted.

I desire to acknowledge my indebtedness, for much of the material to be found in the above account, to the standard writers on anatomy, principally Gray, Morris, Quain, Gerrish, Deaver, and McClellan.

Frederick R. Green.

THORAX. SURGERY OF THE.—Injuries of the Thorax.—Injuries of the chest include contusions and wounds.

Contusions of the thorax are caused by the action of blunt violence, and may result in injury of either the thoracic wall or the thoracic contents, or both. The usual injuries of the thoracic wall are contusions of its soft parts and fractures of the ribs or sternum. The intrathoracic lesions include injuries of the pleura, lung, pericardium, and heart.

The variation in the nature and extent of the specific injuries makes possible a great variety of symptoms in these subcutaneous traumatisms. The symptoms of a local injury may be lost sight of in the general symptoms of shock, which always accompany the most severe forms of thoracic contusions. A condition known as "concussion of the thorax" may occur without demonstrable injury to the walls or contents of the thorax.

Slight ruptures of the parenchyma of the lung, or a mild effusion of blood into the pleural cavity may cause very insignificant clinical symptoms. The patient may expectorate a little bloody mucus. Severe ruptures of the lung and excessive hemorrhage into the pleural cavity will cause marked symptoms of dyspnœa and sometimes extreme anæmia from loss of blood. Injury of a large bronchus may cause pneumothorax. On account of the injury of important organs the prognosis of severe contusions of the thorax is serious. Should, however, the patient withstand the primary shock and the immediate effects of injury of internal viscera, other secondary consequences, such as infection, are not of frequent occurrence.

The treatment of contusions of the thorax is largely expectant and symptomatic. Rest in bed, morphine, ice bags on the chest, and possibly a venous infusion of salt solution are all the measures necessary in most cases. In cases of extreme hæmothorax aspiration of the pleural cavity may be indicated. Arrest of hemorrhage from a large intrathoracic vessel by ligation is usually out of the question.

Wounds of the thorax may be either non-penetrating or penetrating. The former are of special importance only in case of injury of a large artery in the chest wall, such as the internal mammary, or one of the intercostals. Such an injury may result from a stab or gunshot wound. The symptoms would be those of anæmia with local escape of blood, or flatness on percussion over that part of the chest. In order to arrest the resulting hemorrhage it will often be necessary to resect a portion of one or more ribs and their cartilages. In place of ligation of the artery packing the wound with gauze may be substituted. Subsequent removal of the gauze must be done very carefully to avoid secondary hemorrhage. Penetrating wounds of the thorax may cause injury of the pleura, lung, pericardium, heart, or one of the large vessels inside the chest. Injury to the pleura alone or combined with injury of other organs is of very serious moment, both on account of the primary pneumothorax or hæmopneumothorax and of the possible secondary infection of the pleural cavity. Extreme degrees of pneumothorax may be fatal from pressure; but fortunately this is not often the case, the air in the pleural cavity being gradually absorbed. In case of infection of the pleural cavity the resulting exudation may cause pressure on the heart and lungs, resulting in dyspnœa and cardiac weakness. There will also be the general manifestations of sepsis.

Wounds of the lungs may involve penetration of the entire thickness of one or both organs, or merely a superficial surface wound. Most of the wounds are caused by sharp-pointed knives or by fire-arms. The modern bullet frequently traverses the whole thickness of the lung. The primary symptoms of injury of a lung are those of shock from which the patient gradually recovers unless some large vessel has been wounded. In addition dyspnœa is often very pronounced, due usually to a serious hæmo- or pneumothorax. Hæmoptysis is a characteristic symptom, and varies in amount from a little bloody and frothy mucus to abundant hemorrhage.

Emphysema, starting in the vicinity of the external wound, is present in some cases. It is usually confined to the region of the wound, but may in rare cases extend over the greater part of the body. In case of a large wound prolapse of the lung may occur. Symptoms due to infection of the pleura (empyema, abscess of the lung) may arise subsequently, but under expectant treatment are not common. In case a foreign body, such as a bullet, splinter, or tip of a knife-blade, remains behind in the lung, the tendency to abscess formation is more marked. A bullet may heal up in the tissues without marked reaction, and at some subsequent time give rise to severe disturbances. Gunshot injuries of the lung have become much less formidable since the introduction of small calibre projectiles. These bullets make a cleaner cut and smaller channel. In many cases the bullet passes entirely through the lung, leaving behind but slight damage to the parenchyma of the lung and an aseptic wound canal.

The diagnosis of injury to the lung can usually be made from the history of the injury, the position of the wound (in the case of gunshot wounds the location of the entrance and exit), hæmoptysis, pneumothorax, extensive emphysema. The *x*-ray may demonstrate a bullet or other foreign body in the interior of the lung.

The treatment of injuries of the pleura and lung is largely expectant and symptomatic. The use of the probe for determining the depth of the wound should be discarded. The danger of infection is materially increased thereby. The wound and its vicinity should be thoroughly disinfected and a sterile dressing applied without suture of the wound. In case of active hemorrhage from a vessel in the thoracic wall resection of a rib, followed by ligation or packing, may be necessary. Bleeding from a large vessel in the lung is beyond the surgeon's control. Rest and the application of ice bags to the chest will be efficient to stop mild hemorrhages in the lung. Hypodermic injections of morphine are of value for the pain and restlessness. Aspiration in case of hæmothorax is seldom necessary, and should be performed only when the symptoms of pressure are very urgent. The same is true of the pneumothorax. Subcutaneous emphysema usually disappears of itself under an occlusive dressing. If it shows a tendency to spread, it may be treated by multiple incisions into the subcutaneous tissue. The secondary empyema, which is a rare complication, is treated by resection of a rib and drainage. In making an incision for the purpose of drainage, the original wound may if practicable be made use of; otherwise, the incision is made at the place usually chosen for empyema operations. (See farther on, in the section relating to empyema.)

Wounds of the pericardium without involvement of the heart are comparatively rare, and the diagnosis can usually not be made before operation or autopsy. The hemorrhage into the pericardium is not severe as a rule, and does not require special treatment. There may be sufficient to cause indistinctness of the heart sounds and increase in the area of cardiac dulness. Severe pressure symptoms with alarming heart weakness and dyspnœa from excessive hæmopericardium usually mean a wound of the heart itself. Infection of the pericardium may later give rise to a large exudate within the pericardium, which will produce symptoms of pressure and sepsis and demand incision and drainage.

Wounds of the heart may be either superficial or penetrating; in the latter instance one or more cavities of the organ may be opened. Wounds of the apex are the most favorable. The symptoms of a wound of the heart may be sudden collapse and death from hemorrhage. The less severe wounds, however, may give characteristic symptoms and be susceptible of recovery either spontaneously or after operation. The external wound does not show anything typical. There may be little or no hemorrhage from it; or, in case of large wounds, large amounts of arterial or venous blood may escape. The position of the wound is important in making the diagnosis of injury of the heart. Hemorrhage into the pericardium gives rise to more or less marked symptoms of pressure upon the heart and lungs. The heart sounds are inaudible. The pulse becomes irregular and weak and there is severe dyspnœa. The patient is restless and has a feeling of anxiety. In case the patient survives the primary shock and the effects of hemorrhage, the secondary symptoms of infection, particularly of the pericardium, may supervene. Suppurative pericarditis, though fortunately a rare complication, may prove a dangerous one, and its early recognition is imperative. The symptoms of pressure of the purulent exudate upon the heart and the signs of sepsis are usually sufficiently well marked to make the diagnosis possible. Bullets may remain within the heart or pericardium for years without producing circulatory disturbances or infection. G. Fischer collected 452 cases of wounds of the heart with 380 deaths and 72 recoveries. Death was immediate in 104, and in 270 it occurred after intervals varying from one hour to nine months.

The treatment of wounds of the heart is usually symptomatic, but in some cases active interference becomes necessary. Complete rest in a recumbent position is combined with the administration of morphine, the application of an ice bag over the heart, and, when necessary, the judicious use of some heart stimulant, such as digitalis. In extreme collapse the infusion of salt solution may be called for. Severe pressure of the blood within the pericardium upon the heart may demand aspiration or incision. Different points in the chest wall have been chosen for making the incision to expose the pericardium. A favorite place is the fourth or fifth intercostal space close to the sternum, with resection of the fourth or fifth costal cartilage. The point of entrance of the instrument which inflicted the wound may be made use of in making the incision. Incision is preferable to puncture, as it is much more effective and involves less danger of injuring the heart. Furthermore, an incision of the pericardium makes possible suture of the heart, should this be necessary. The insertion of sutures into the heart is usually a difficult procedure, but has been successfully accomplished in a number of instances. Silk or catgut may be used. The introduction of one or two long sutures facilitates the insertion of the other stitches. The sutures should pass only through the muscle tissues and not enter the cavity. The most favorable wounds for suturing are the smaller ones of the anterior surface of the right or left ventricle. Wounds of an auricle or those which pass through both ventricular walls cannot as a rule be sutured. The indications for attempting suture of the heart are progressive bleeding into the pericardium, or externally, with increasing anaemia or symptoms of pressure on the heart. Out of 34 cases of heart suture collected by Sherman, 5 died on the operating table of hemorrhage, 10 died very soon after operation, and 13 recovered.

For fractures of the ribs and sternum see under *Fractures*.

Inflammatory Diseases of the Chest Wall.—Cold abscesses are generally tuberculous in origin and arise usually from some carious process in a rib. The thoracic and dorsal muscles easily permit of gravitation and burrowing of the pus so that the original focus in the bone may be a considerable distance from the abscess itself. The symptoms are slight. The abscess causes a fluctuating swelling, varying in size, over which the skin is normal. The treatment may be either aspiration with injections of iodoform and glycerin, or incision and drainage.

Osteomyelitis of the Ribs and Sternum.—Acute osteomyelitis of these bones is rare. Typhoid fever is occasionally complicated by subacute osteomyelitis of the ribs. The treatment is in general the same as in other bones.

Tuberculous osteomyelitis is far more commonly localized in the ribs or sternum. The process leads to the formation of a tuberculous abscess, which either breaks through the skin in the vicinity, forming a fistula leading down to the focus in the bone, or burrows under the muscles, forming a cold abscess, which comes to the surface at some more distant point.

The treatment consists in dividing the fistulous tracts and resecting the rib. In case of long fistulous tracts the injection of iodoform emulsion may be substituted. Extensive resections of the sternum are sometimes necessary.

Surgical Diseases of the Pleura.

Empyema.—Inflammations of the pleura belong in the province of surgery only when the exudate is purulent in character. The purely serous exudates and transudates are treated by internal medication and aspiration (paracentesis thoracis). Should, however, a serous exudate become suppurative, the more radical surgical measures of thoracotomy, with or without resection of a rib, have to be resorted to.

The *ætiology* of empyema is varied. The infection may gain access to the pleura through an external wound, through the blood or the lymphatics, and finally by direct extension from a neighboring organ, most commonly the lungs. It may thus represent a purely local suppurative process or be a part of a general sepsis. An abscess within the abdomen may rupture through the diaphragm and cause an empyema, or a suppurative process in the neck or chest wall may extend directly or through the lymphatics to the pleural cavity. The bacteriological examination of the exudate has shown the presence, in different cases, of the pneumococcus, the streptococcus, the staphylococcus, and the bacillus of tuberculosis. Pneumococcus infections are the most common ones in children, while in adults the streptococcus is the most frequent cause, with the bacillus tuberculosis next. The character of the infection determines to a large extent its virulence. Tuberculous cases are by far the most unfavorable.

The *symptoms* of empyema are those of pressure produced by a fluid contained in a closed cavity, and the manifestations of absorption of septic materials. Pressure may cause displacement and interference with the functions of the lungs and heart. The septic absorption causes fever, emaciation, and ultimately death unless the pus finds a spontaneous or artificial escape. Spontaneous discharge of pus, which is unusual, may take place through a bronchus or the chest wall. Even when such an outcome occurs the escape of pus is not complete, and in order to heal a resulting fistula or expectoration of pus, an operation is usually necessary. The longer the operation is delayed the greater the danger of sepsis, and in case of recovery the longer the healing process will be. In chronic cases the pleural surfaces become enormously thickened, the lung, from continued pressure, becomes greatly contracted, and the enclosed abscess cavity tends to persist owing to the rigidity of its walls.

The *treatment* of empyema consists in prompt and thorough evacuation of the purulent exudate, followed by drainage of the cavity (thoracotomy). For this purpose resection of a portion of a rib is advisable in order to gain better access to the cavity and secure more complete drainage. In children incision through an intercostal space may be sufficient. The rib chosen for resection may be either the eighth, ninth, or tenth posteriorly, to the outer side of the long dorsal muscles, or the fifth or sixth in the axillary line. The advantage of the first location is that the abscess cavity is opened at its lowest portion and in the usual recumbent position the drainage is the best possible. On the other hand, the ascent of the diaphragm may tend to displace or compress the drainage tube. In the axillary line the ribs are more accessible, thus making the operation easier, but the drainage is inferior and hence the healing process will be slower. In either locality the portion of rib in question is exposed by an incision along the rib, three or four inches in length. The periosteum is divided in the line of the skin incision and separated from the outer and inner surfaces of the rib by means of a pericostal elevator. Care must be taken not to injure the intercostal artery which runs along the lower border of the rib. The latter having been exposed, a piece, two inches in length, is removed with bone-cutting forceps or a Gigli saw. The exposed pleura should now be punctured with an aspirating needle to make sure that pus is really present; and if pus is found, a pointed knife is thrust into the distended cavity. The finger may now be inserted for the purpose of exploring the cavity and removing solid pieces of lymph which might obstruct the drainage tube. The pus having been evacuated, irrigation with 1 to 10,000 bichloride solution or 1 to 4 peroxide of hydrogen followed in most cases by salt solution may be practised, although this is not necessary except when the exudate is very foul. One or two thick-walled drainage tubes are now inserted and a safety-pin is passed through their outer end to prevent them from slipping into the cavity. Finally a voluminous gauze and cotton dressing is applied and held in place by a muslin bandage or binder. During the after-treatment the cavity may be washed out with some harmless solution and the drainage tubes gradually shortened. In order to accelerate expansion of the lung expiratory exercises, such as blowing air into a rubber ball, may be employed. Healing of the thoracic opening may be very slow, but ordinary cases heal even after the lapse of months. Cases which had existed a long time before operation and tuberculous cases may not heal, and will then require further operative treatment. The cause of failure of healing in those cases is the existence of a chronic abscess cavity with rigid walls which can neither be filled up by expansion of the lung nor contract by shrinkage of the surrounding parts. In case the cavity persists the patient suffers from the effects of septic absorption, particularly if the fistulous opening becomes stopped up. In case of tuberculosis the general symptoms are more marked and the local process may spread to the neighboring ribs and other adjoining parts. For this reason it is desirable to bring about a radical cure of the conditions which otherwise may continue indefinitely. Several operations have been devised for this purpose which have as their common object the contraction and obliteration of the abscess cavity. *Estlander's operation* (thoracoplasty) consists in the subperiosteal resection of a piece from all the ribs covering the cavity. The number resected will depend upon the size of the cavity, but it is better to resect too many than too few. Removal of a portion of the ribs in question makes the thoracic wall much more movable, and thus enables it to come in contact with the visceral pleura, and finally unite with it. *Schede's thoracoplasty* consists in removal not only of portions of the ribs, but also of the thickened parietal pleura as well. For this purpose a curved incision is made from the outer border of the pectoralis major muscle at the level of the fourth rib to the tenth rib in the posterior axillary line. From here the incision ascends in a curve and runs along the vertebral side of the scapula. The skin and muscles are dissected up, exposing the ribs, which are removed subperiosteally from the costal cartilage to the tubercle. The thickened parietal pleura is now removed with forceps and scissors, leaving behind a shallow gutter-shaped cavity which is scraped out and then covered with the flap of skin and muscle. The wound is sutured in front, but left open and packed behind. This operation is the most successful one for large cavities: smaller ones can usually be covered by the Estlander method. Délorme practised "decortization of the lung" for chronic empyema, and a number of cures by this method have been reported. His operation consists in reflecting a flap of skin, muscle, and bone, and then removing both pleural surfaces with the finger or scissors. The flap is then returned to its place. The hemorrhage from the surface of the lung is often excessive and requires postponement of the operation to a second sitting. Most cases of chronic empyema can be cured by one of these forms of operation. Estlander's is sufficient for the smaller cavities, while Schede's is designed for the extensive cavities and the tuberculous cases. Délorme's operation is still in the experimental stage.

Surgical Diseases of the Lung.

The most important diseases of the lung for the surgeon are abscess, gangrene, and bronchiectasis. Tuberculous cavities are only seldom adapted to operative treatment.

Abscess of the Lung.—The causes of pulmonary abscess are acute pneumonia, infectious embolism, foreign bodies in the lung, wounds, and perforations of a suppurative process in the neighborhood. The characteristic sputum of abscess of the lung is pure creamy pus without marked odor. Microscopic examinations show the presence of elastic fibres and hæmatoidin crystals. Fever is present and there are physical signs of a cavity in the lung which is alternately full and empty. Without operation the prognosis is unfavorable.

The treatment consists in opening the abscess as soon as the diagnosis is made. The prognosis of operation is best in case of abscess following pneumonia and much worse in one due to a foreign body or to embolism. The thorax is opened by an incision similar to that made for empyema, one or two ribs being resected for the purpose of gaining more room. In place of resecting ribs a flap consisting of skin, muscle, and bone, can be reflected and then replaced after completion of the operation. The costal pleura having been exposed it should be determined whether or not adhesions exist between this and the visceral pleura. Such adhesions are necessary to prevent a pneumothorax or escape of infectious contents into the cavity. To determine the presence or absence of adhesions a fine aspirating needle may be thrust into the pleura. If it moves back and forth freely there are no adhesions present. In case of adhesions the movements of the needle are slight or absent. If not already present they should be artificially produced by packing gauze upon the costal pleura, and leaving it in place for several days, or by suturing the two surfaces. The adhesions having been obtained the presence of pus is ascertained by means of an aspirating needle thrust into the cavity. If pus is present an opening into the lung is made with a pointed knife or the thermo-cautery. The latter method is followed by less hemorrhage and the opening is more likely to remain patent. A drainage tube is inserted into the abscess cavity and gradually shortened as the healing process progresses.

Gangrene of the Lung.—When circumscribed, gangrene of the lung may be the object of surgical treatment. Its etiology is much the same as that of abscess; it occurs particularly in alcoholic or diabetic patients, or those in poor general health. It is distinguishable from abscess chiefly through the character of the sputum. This is extremely foul-smelling and contains particles of broken-down lung tissue. The different forms of gangrene can be treated only by medicinal means, such as inhalation of carbolic acid or turpentine, and the internal administration of creosote, etc. The prognosis in these cases is usually hopeless, the patients succumbing to the septic absorption. Localized foci of gangrene should be attacked in the same way as abscess by thoracotomy and resection of one or more ribs. The good effects upon the general condition of free evacuation of the contents of the gangrenous cavity are almost instantaneous, and the removal of the foul odor and taste is an immense boon to the patient. Tupper's statistics show 74 cases of pneumotomy for gangrene with 60 per cent. recoveries. Lenzbarzt has collected 118 cases that were operated upon, of which 94 were cured and 54 died—*i.e.*, 63.5 per cent. of cures. Villière's statistics show that with internal treatment from 75 to 80 per cent. die. This seems an excellent showing for the operative treatment.

Bronchiectatic Cavities.—In recent years the drainage of cavities resulting from bronchiectasis has been performed in a number of instances with satisfactory results. This is true only of a single cavity, or of two or more which lie closely adjacent. The diagnosis is made chiefly from the history, the character of the sputum, and the physical examination of the chest. The odor is not so intense as in gangrene, and there is an absence of degenerated tissue elements. The technique of the operation is much the same as in abscess and gangrene. After exposing the pleura adhesions are produced by packing or by sutures and the pus is sought for with an aspirating needle. The thermo-cautery is the best instrument for cutting through the layer of healthy lung before entering the cavity. Drainage is provided for in the usual way. The beneficial effects of removal of the purulent focus are often surprising. Some bronchorrhœa is likely to persist, but it can be kept under control by proper hygienic measures and and by the use of expectorants.

Diseases of the Mediastinum.—The diseases of the mediastinum are acute and chronic mediastinitis, and mediastinal tumors.

Mediastinitis.—The etiology of inflammations in this region includes traumatism, extension from adjacent organs, and tuberculosis. The anterior mediastinum is by far the most frequently attacked. The symptoms of the acute and chronic forms are much the same except that in the former they are more intense. Pain is present in all cases and is located behind the sternum, from which it radiates to the shoulder blades. The sternum is often tender on pressure and may become red and œdematous. Fever is present particularly at the beginning, and in the acute cases may be accompanied by chills and sweating. As soon as pus has formed pressure symptoms may make their appearance, including dyspnœa and heart weakness. The abscess may finally work its way to the surface and point either in some intercostal space close to the sternum or at some more distant part. Rupture into the diaphragm, trachea, or pleural cavity may also occur. The treatment consists in evacuating the pus at the place where the abscess points, or in opening the anterior or posterior mediastinum. The anterior mediastinum is opened by resection of one or more ribs or costal cartilages, and the adjacent sternum. The posterior mediastinum has only seldom been attacked. On the cadaver it has been shown that removal of a transverse process of a vertebra and the underlying piece of rib gives a good opening for the discharge of pus.

Tumors of the mediastinum include the benign and malignant. Glandular enlargements form a goodly percentage of these new growths. Some of the tumors are primary, others are secondary. The benign tumors include fibroma, lipoma, and dermoid cysts. The malignant tumors, both carcinoma and sarcoma, may have their origin in the bronchial glands or in the bronchi themselves. In all varieties the symptoms are practically the same, and are chiefly those of pressure. The heart, lungs, large vessels, nerves, œsophagus, and trachea may be compressed and their function impaired. Furthermore, the chest wall may be pushed forward and ultimately the tumor may come to lie beneath or perforate the skin. Malignant tumors run a more rapid course than the benign, and may cause death before the tumor has appeared externally. Percussion is dull or flat over the tumor when it is situated close behind the sternum. Pressure upon the recurrent laryngeal nerve causes paralysis of the vocal cord on the same side. Pressure on the pneumogastric may result at first in slowing of the pulse, later in acceleration of the same.

The differential diagnosis from aortic aneurism can usually be made from its history and from the presence in the latter of arteriosclerosis, aortic insufficiency, friction sounds, etc.

As regards the prognosis the differentiation of the benign from the malignant tumors is of extreme importance. The malignant are the more common, and whether primary or secondary can usually be recognized by their more rapid growth, by the presence of glandular enlargements, by the greater severity of the pain, and by the rapid loss of flesh and strength.

The treatment may be begun by the internal administration of potassium iodide or arsenic, and in case of syphilitic lymphomata, malignant lymphomata, and some sarcomata a diminution in the size of the tumors will result. Other cases will call for active surgical treatment, and this should not be delayed too long either in the malignant or in the benign forms. The operation is the same as in suppurative mediastinitis, except that more room will be necessary for removing the growths than for opening the abscess. Excision of several ribs and part of the sternum or temporary osteoplastic resection of ribs by means of a flap of skin, muscle, and bone furnishes a good exposure of the anterior mediastinum. Through such an opening the tumor masses are enucleated, care being taken not to injure the pleura or the pericardium. If such an accident occurs, the opening is closed at once by suture or the wound packed, and the operation put off to a second sitting. Excessive hemorrhage may be another reason for postponing the completion of the operation. The benign as well as the malignant tumors may require extensive dissection, although adhesions with adjacent structures are more intimate in the malignant forms.

Diseases of the Pericardium.—As in the pleura exudations occasionally take place within the pericardium. Of these the suppurative form will demand surgical interference. Collections of serum or of blood may be removed by aspiration,but, should this not be sufficient, incision may be resorted to. Purulent collections, just as in empyema, require for a cure incision and drainage. Puncture and aspiration are frequently resorted to in making the diagnosis of the presence and character of the exudate. A safe place for puncturing the pericardium is at a point between the fifth and sixth ribs, close to the sternum. The third or fourth intercostal space can also be chosen. Care must be taken not to injure the internal mammary artery which lies at a distance of from 1 to 2.5 cm. to the outer side of the sternum. Puncture is performed with an aspirating needle or a trocar. As the heart may be pushed forward by the exudate behind and thus lie close to the anterior thoracic wall, care must be exercised in not injuring that organ. The instrument is thrust in cautiously in an upward direction, and it is often possible to feel the heart come in contact with the point of the needle. Délorme collected eighty-two cases of puncture of the pericardium with twenty-eight cures.

Incision of the pericardium may be performed through a variety of incisions. Ollier's incision seems the simplest and answers the purpose. The incision runs from the middle of the sternum along the centre of the fifth costal cartilage. The latter is dissected free, resected with a knife or bone-cutting forceps, and the internal mammary artery tied. In case sufficient room is not obtained, a piece of the sternum is resected. Another incision (Délorme) begins 1 cm. from the left border of the sternum and runs from the fourth to the seventh costal cartilage. Two short lateral incisions are made outward from each end of the longitudinal one, and the flap is turned back. The cartilages of the fifth and sixth ribs are resected, care being taken not to wound the internal mammary artery. Drainage is provided for by means of a rubber drainage tube inserted into the cavity. Among thirty-five cases of suppurative pericarditis operated upon by incision and drainage, Kobert found that forty-three per cent. recovered.

Benjamin T. Tilton.

THOROUGHWORT.—(*Eupatorium* U. S. P.; Boneset.) The dried leaves and flowering tops of *Eupatorium perfoliatum* L. (fam. *Compositæ*). This is a widely spread species, growing in the greatest abundance about the borders of ponds and brooks, and in wet places generally, from Canada to Florida, and from the eastern to the western side of this country. It is a handsome, large, perennial herb, with a hairy, rather simple stem, growing from two to four or more feet high, large, dark green and completely connate pairs of rough hairy leaves, and flattened, complex, cymose clusters of small heads of minute creamy-white flowers.

Description of Drug.—Leaves opposite, the two united by their broad bases, the uppermost often distinct, those of the inflorescence mostly alternate and greatly reduced; 8–15 cm. (3–6 in.) long and 1.5–5 cm. (⅔–2 in.) broad, tapering regularly from near the base to an acute apex, crenate-serrate, above bright green or somewhat yellowish-green, rugose and finely bullate; underneath yellowish gray green, densely short hairy and resinous dotted, the prominent, rounded, crooked, fine veins conspicuously reticulated; flower-heads very numerous, in broad corymbs, the branches rough hairy; mature involucre campanulate, the imbricated scales lance-oblong, obtusish, green, hairy, the inner longer and with whitish tips and margins; flowers of the head about ten to sixteen, tubular, yellowish white, the pappus in a single row, white, bristly; odor weak, aromatic; taste bitter, astringent, aromatic.

The constituents of thoroughwort are chiefly the bitter glucoside eupatorin, which is soluble both in alcohol and in boiling water, a very small amount of volatile oil, a glucosidal tannin, which constitutes the coloring matter, and another tannin. There are also gum, resin, and ordinary plant constituents. The presence of an alkaloid has been reported, but this subject requires further investigation.

USE.—Boneset has been long used in the United States as a tonic and antiperiodic, and even as an emetic, but always more of a family medicine than one prescribed by physicians. Since the beginning of the last century it has fallen very much into disuse. In small doses thoroughwort is a mild bitter tonic, like the chamomiles and others in the same family, but with less aromatic character than most of them. It is also a good deal like horehound in the *Labiatæ*. In larger doses, especially in hot infusion, it is diaphoretic, possibly diuretic, and is still occasionally used, followed by a sweat under blankets, to abort colds, and in the beginning of most acute diseases. In very large doses (an infusion of an ounce or so) it is a nauseating emetic. Doses as large as can be borne by the stomach, repeated for some days, have had a considerable reputation in the country, and have a little real value, in the treatment of intermittent fever and other malarial manifestations.

In domestic practice thoroughwort is usually given in the form of a decoction, especially when its diaphoretic, antirheumatic, or antiperiodic action is desired. Physicians also often prescribe it in that way, though more often at the present time in the form of the fluid extract. The dose of the latter, of which 1 c.c. is the equivalent of 1 gm. of the drug, is 10–15 minims as a tonic, 1–4 c.c. (fl. ʒ $\frac{1}{4}$–i.) as a diaphoretic and antiperiodic, and two or three times as much as an emetic.

ALLIED SPECIES.—The genus *Eupatorium* comprises many hundreds of species, a large number of which, in various countries, are employed similarly to the above. Numerous plants belonging to related genera have similar properties. (See *Compositæ*.) *Henry H. Rusby.*

THREE SPRINGS.—Huntingdon County, Pennsylvania.

POST-OFFICE.—Three Springs. Hotels and sanitarium.

ACCESS.—Take the Pennsylvania Railroad (main line) to Mount Union, Pa.; thence take East Broad Top Railroad to springs.

The village of Three Springs is located in a valley formed by Jack's Mountain, 2,220 feet high, and Care Hill, 2,210 feet in altitude. The place takes its name from the presence of three mineral springs, situated about one hundred feet apart, and forming the corners of an equilateral triangle. The springs are known as "No. 1," "No. 2," and "No. 3." They have been known and used for many years, but it was not until 1891 that they came under control of the present proprietor, who has brought them to an advanced state of development as a resort. Spring No. 1, the most important of the group, flows about one thousand gallons of water per hour, having a temperature of 55° F. It is used commercially under the name of the Hygeia Natural Mineral Water, and is shipped in five-gallon demijohns. The following analysis was made in 1895 by Prof. G. G. Pond, of the Pennsylvania State College:

Spring No. 1 (Three Springs). One United States gallon contains (solids): Calcium bicarbonate, gr. 31; calcium sulphate, gr. 53.63; magnesium sulphate, gr. 33.51; sodium sulphate, gr. 5.91; sodium chloride, gr. 0.35; lithium sulphate, gr. 0.02; potassium sulphate, a trace; silica, gr. 1.15. Total, 128.6 grains.

Gases: Carbonic acid, cub. in. 5.47; oxygen, cub. in. 1.72; nitrogen, cub. in. 3.85. The water is bright, sparkling, and palatable, and entirely free from organic impurities. It is an efficient laxative and mild diuretic and has been found beneficial in cases in which activity of the emunctories is desirable. The water has been used with success in cases of obesity and in uræmia and general anasarca, as well as in local dropsies. In habitual constipation a systematic course of the water is often curative. It is also beneficial in other disorders requiring a sulphureted saline water. The sanitarium at Three Springs is kept open all the year. *James K. Crook.*

THROMBOSIS. DEFINITION.—Thrombosis is a pathological state or process in which there is a deposit within the heart or vessels, during life, of solid material originating in transformation of the blood.

The solid mass or plug thus produced is called a *thrombus*.

It used to be taught that thrombosis was caused by the coagulation of the blood, but fuller researches, more especially those of Eberth and Schimmelbusch, have proved that many thrombi, at least at first, are due to the agglutination of blood platelets or of corpuscles without fibrin formation, so that it is more correct to adopt a wider definition, such as that given above.

VARIETIES OF THROMBI.—Any or all of the formed elements of the blood or their derivatives may enter into the composition of thrombi, viz., red corpuscles, leucocytes, blood platelets, and fibrin.

Red Thrombi.—These are produced in stagnating blood and are strictly comparable to clots formed outside the body, being composed of fibrillated fibrin, red and white cells, in much the same proportion as in ordinary clots.

White Thrombi.—Thrombi deposited from the circulating blood are generally of the white variety. The characteristic color, whence they derive their name, is due to the presence in excess of fibrin, leucocytes, and platelets. It is not, however, uncommon to find *mixed thrombi* in which there is an admixture of red cells, giving them a somewhat reddish tint. When recent, white thrombi under the microscope are composed of granular material having the form of clumps or strands of irregular size and shape which are embedded in fibrin, leucocytes, and a certain number of red cells. The granular matter in question is composed of altered blood platelets. The fibrin has frequently a distinct fibrillated structure, and is particularly abundant at the periphery of the masses of platelets, sending anastomosing branches into their substance or forming a loose meshwork in which red cells are entangled.

Fibrin Thrombi.—These are not infrequently found in inflamed areas, usually in the smaller vessels. They may be seen particularly well in the vessels of the lung in croupous pneumonia. According to K. Zenker, who has described them in detail, whorls or brush like tufts of coarse fibrin may be seen springing from the wall of the vessel. These appear to radiate from a definite centre composed of degenerating material, such as endothelial cells, leucocytes, blood platelets, or débris. The amount of deposit is not usually sufficient completely to block the vessel. In old white thrombi also the cellular elements degenerate and are replaced by fibrin.

Leucocytic Thrombi.—As has been already hinted, leucocytes enter into the formation of a large proportion of white and mixed thrombi; but thrombi composed almost entirely of white cells are also to be met with, particularly in areas that are acutely inflamed. In this case the condition is really a capillaritis, arteritis, or phlebitis, and the plug is due to the accumulation of leucocytes attracted to the spot by chemotaxis. Somewhat similar masses are seen within the vessels in cases of leukæmia, but these are perhaps not strictly to be regarded as thrombi.

Hyaline Thrombi.—For the recognition of this form we are indebted to von Recklinghausen. Hyaline thrombi are found chiefly in the capillaries, but also in the smaller veins and arteries. The lumen of the affected vessel is filled with a homogeneous, translucent, and refractile substance, without color, or at most having a faint yellowish tinge, which gives the microchemical reactions for fibrin. This variety is found more especially in toxic and infective conditions and after exposure to heat and cold. The most striking examples of it, according to Welch, are to be found in the renal capillaries of swine dying of hog cholera. It is also met with in pneumonia, hemorrhagic infarction, frost-bite, and eclampsia.

The Chemico-Physics of Thrombosis.—Until we are able to give a more complete explanation of the process of coagulation of the blood, we shall still be more or less in the dark as to the nature of thrombosis. As with all vital and semi-vital processes, the subject is beset with difficulties. According to the most painstaking investigators coagulation is a chemical process whereby the interaction of certain substances results in the precipitation of insoluble material. According to Schmidt ("Zur Blutlehre," Leipsic, 1893) the following are the determining factors: (1) Soluble proteids of the nature of globulin, with their derivative fibrinogen. (2) A fibrin ferment to act upon the substances just mentioned. (3) Various neutral salts, but especially those of calcium, which form insoluble compounds. Arthus and Pages (*Arch. de Phys.*, ii., 1890) have shown that without the intervention of calcium salts fibrinogen cannot give rise to fibrin, for if potassium oxalate be added to fresh blood in sufficient amount to precipitate the calcium salts, clotting will not occur; while if calcium salts be restored, clotting will rapidly take place. Pekelharing (*Festschrift f. Virchow*, Berlin, 1891, and *Deutsche med. Woch.*, 1892), basing his opinion on the fact that a nucleo-albumin can be isolated from the plasma, which when brought in contact with fibrinogen and salts of calcium produces a typical clot, believes that the fibrin ferment or "thrombin" of Schmidt is a combination of nucleo-albumin and calcium. When this is brought into contact with fibrinogen the calcium radical unites with a portion of the fibrinogen molecule to form an insoluble salt, fibrin. Fibrinogen and calcium salts are to be found in the blood plasma, while the nucleo-albumin is a product of the disintegration of the leucocytes and perhaps the hæmatoblasts. In terms of this theory, then, fibrin is an end-product of the chemical interaction of nucleo-albuminate of calcium and fibrinogen.

Besides this, however, the researches of Lister, Brücke, Baumgarten, and Freund have proved that certain mechanical principles enter into the question of coagulation. If, as was done by Lister, a section of a large vessel containing blood be isolated between double ligatures and removed, the blood will remain fluid for hours; and further, if the vessel be divided transversely into two so as to form, as it were, two test tubes, the blood may be poured from one portion to the other almost indefinitely without coagulating. The reason for this is not entirely clear. But Freund has shown (*Wiener med. Jahrb.*, 1888) that, provided decomposition be prevented, blood which has been received into glass vessels smeared with vaseline will remain fluid for a long time. A similar result follows if blood be dropped into some perfectly bland fluid such as oil. Freund thinks that when the vessel is not lubricated in this way the surface of the glass destroys some of the red corpuscles, and that this initiates coagulation. However this may be, the experiment at least shows that what are at first sight trivial changes in the condition of the vessel wall are sufficient to induce coagulation. However, something more than mere contact with a foreign surface appears to be necessary. Changes must be present of such a nature as to promote adhesion between the vessel wall and the corpuscles, especially the red cells. Small glass balls, presenting a smooth, unirritating surface may be introduced into the blood vessels with impunity, as in Zahn's experiment (*Festschrift f. Virchow, Internat. Beitr.*, ii., p. 199); while if needles or other sharp objects be inserted, the blood platelets are precipitated and thrombosis is rapidly induced. Anything, therefore, that impairs the integrity of the vessel wall, be it in the slightest degree, may on occasion determine thrombosis.

It may be asked why it is that coagulation of the blood does not take place under the conditions of normal existence. All the elements for the production of fibrin are in fact present, for there is constant disintegration of the red cells with liberation of nucleo-proteid; but so long as the vessel walls remain intact, the amount of nucleo-proteid is but small, and it is quickly neutralized or metamorphosed and thus rendered innocuous. The fact that it is difficult to produce thrombosis by the injection into the circulation of nucleo-albumins proves that up to a certain point the body is able to protect itself against coagulation. Lilienfeld has further shown that under certain circumstances during disintegration of leucocytes a proteid is formed, which he terms *histon*, that has the power to prevent clotting.

Numerous experiments, as well as clinical observations, have led us to realize that a variety of factors are concerned in the process of thrombosis. Most are, I think, agreed that the following points are of cardinal importance, although there is not always unanimity as to the relative value of each: (1) Alterations in the vessel wall, whereby the blood is brought into contact with an abnormal surface. (2) Slowing or other irregularities of the blood current. (3) Changes in the blood itself. As the sequel will show, it is beyond question that the action and reaction of the various factors mentioned are intimately bound up together.

It may be inferred, and rightly, from the experiments above referred to, that gross physical changes in the condition of the vessel wall are of powerful import in the causation of thrombosis, particularly if they be such as to impair the continuity of the intima or produce obstruction. Injuries or disease of the vessel walls, and foreign bodies of all kinds within the lumen, such as needles, bones, wire, lime salts, bits of tumor, and parasites, may act in this way. Advantage is taken of this fact in the well-known treatment of aneurisms by the insertion of fine wire. The thrombus itself often acts as a foreign body, a fact which explains its tendency to spread. Yet it is frequently observed at autopsies that the most extensive disease with roughness of the intima may exist, as in atheroma, without the formation of a thrombus. Again, Zenker has noted that degenerating endothelium often forms a nucleus for the deposition of fibrin, so that a star-like clot is formed. If, too, we inflict an aseptic injury on the valves of the heart in an experimental animal, relatively little thrombosis results. Should we, however, inject pyogenic micro-organisms at the same time, we get the most pronounced effects. Such observations suggest that in thrombosis, besides mechanical factors, chemical changes have to be taken into account, and it would appear necessary to assume certain specific properties on the part of the intimal cells and the injured tissue. This is further indicated by numerous experiments which have proved that certain substances introduced into the blood have the power of inducing coagulation. Such are thymus extract, laky blood, defibrinated blood, ether, tissue juices, snake venom, and biliary salts, among others. These substances probably act by affecting the vitality of the intimal cells, or possibly, as some think, by liberating the fibrin ferment. It is by no means proved, however, that the clots thus produced are identical with ordinary thrombi. In fact, there is every reason to think that they are not. It must, nevertheless, I think, be admitted that circulating toxins or perverted metabolism in the blood induce important alterations in the properties of the intimal cells, for, as we know, there is a decided tendency in many infective and cachectic states for thrombosis to occur. It is, perhaps, mainly in this way that the so-called "ferment thrombi" are produced.

Slowing of the blood stream has been referred to as one of the factors concerned in the production of thrombi. This in itself cannot be of prime importance since numerous experiments, notably those of Glénard and Baumgarten, have shown that the circulation may be completely obstructed within a vessel, by the application of aseptic ligatures, without thrombosis resulting. It is, nevertheless, a fact that thrombi are apt to form just where the circulation is feeblest, as in the veins and diverticula of the vascular apparatus. It would seem to be necessary, however, that some lesion of the vessel wall should exist as well, and this as a matter of fact is generally present, owing to the impoverished nutrition resulting from the impaired blood flow. A slow circulation, therefore, determines the place rather than the fact of thrombosis. Baumgarten, indeed, attributes more importance to eddies in the blood than to mere slowing of the stream, and has laid stress upon the fact that thrombi are commonly formed in culs de sac, dilated chambers (dilatation thrombi of Virchow), and about the valves of the veins, in fact, where eddies are naturally produced. He has, moreover, shown that a carefully tied ligature, leading as it does to stagnation of the blood, need not necessarily result in the formation of a thrombus unless the inner lining of the vessel be ruptured.

Two main forms may be differentiated in this group of so-called "stagnation" thrombi, viz., those found in conditions of great prostration and cardiac weakness, called by Virchow, who regarded them as due to marasmus, "marantic" thrombi, and those due to local circulatory disturbances, as in aneurisms and varices, and in obstruction of the vessels. Not all the so-called "marantic" thrombi can be rightly attributed to marasmus, as it is impossible in such cases to exclude vitiated conditions of the blood and degenerative changes in the lining endothelium. Many of them are, no doubt, toxic in nature, due to accidental or terminal infection.

Little is known as yet with regard to the changes in the blood that favor thrombosis. Changes are, however, undoubtedly present in such cases as the infectious fevers, in snake-bite, arsenical poisoning, severe burns, and trauma. Weir Mitchell long ago pointed out that one of the characteristic features of snake-bite was the agglutination of the red corpuscles, and similar properties have been abundantly shown by more recent experiments to be possessed by a number of substances of which may be mentioned abrin, ricin, the blood serum of another race of animal, the toxins of certain bacteria as those of typhoid, hog cholera, pneumonia, and diphtheria. It is probable, therefore, that the so-called "ferment" thrombi and the agglutinative or hyaline thrombi are largely due to a toxin acting upon the red cells so as to destroy them and produce a uniform conglomerate.

In other ways, too, thrombosis may be promoted. In some diseases in which there are marked leucocytosis and an increase in the fibrin content of the blood, thrombosis is not infrequent. In others, like typhoid, in which there is leucopenia, thrombi are rare, at least during the height of the disease. When they are present in typhoid, it is only in the later stages, when the circulation is feeble, the vessels are relaxed, and there is an increase in the number of leucocytes, with possibly a secondary infection. It is here, again, impossible to exclude changes in the endothelium.

THE MODE OF DEVELOPMENT OF THROMBI.—It is a common event to find within the heart and great vessels at autopsy large soft clots of varying appearance. These are produced during the death agony or shortly after. When clotting has been rapid, a uniform, dark red, soft coagulum is formed, not differing specially from that produced in the process of extravascular coagulation. In cases in which clotting is slower, the red cells, being specifically heavier than the white, sink to the bottom, and the uppermost layers of the clot form a soft, yellowish, or buffy portion, while the deeper parts are of a reddish, raspberry-jelly-like appearance. In cases in which during life leucocytosis has been marked, as in inflammatory rheumatism and pneumonia, large yellowish, oily looking clots are produced. Such clots are readily distinguished from those produced during life by the fact that they lack the firm granular structure, and are only loosely adherent to the wall of the heart or vessel.

Very different are the real thrombi. When the blood is stagnating or the circulation prevented, red thrombi are formed, provided that the ordinary conditions favoring the deposition of fibrin are operative. Under the microscope these thrombi consist of masses of red cells, among which coarser or finer strands of fibrin can be seen together with an occasional leucocyte. At first the thrombus is soft and juicy, but later it becomes firm and dry, and presents a paler or a brownish or rusty appearance.

Zahn's researches (*Arch. f. path. Anat.*, Bd. xcvi., 1884) have shown that the essential factor for the production of a white thrombus is a continuous circulation. In the circulating blood stream two regions are to be distinguished, an axial and a peripheral. The axial stream contains the red and white cells, while the more slowly moving peripheral current is chiefly plasma with an occasional leucocyte floating in it. Should the rapidity of the circulation be diminished, the number of the white cells in the peripheral zone is notably increased, and in the more extreme cases blood-platelets begin to make their appearance. The exact part played by the blood-platelets has given rise to much debate. Bizzozero (*Centralb. f. d. med. Wiss.*, 1882, 1883) believed that in the course of their destruction they liberated the fibrin, but his conclusion has been by no means generally accepted.

If, as Eberth and Schimmelbusch did (*Arch. f. path. Anat.*, Bd. ciii., cv., cviii.), we injure the mesenteric vessels in a warm-blooded animal, as, for instance, by silver nitrate, blood platelets are quickly deposited and become massed at the site of injury (conglutination), and eventually are fused into a more or less coarsely granular or homogeneous material (viscous metamorphosis). In some cases these deposits are cast off into the general circulation, but frequently they keep on enlarging until the lumen of the vessel becomes occluded. An occasional red or white cell can be made out in the mass, but these are clearly accidental, and have nothing to do with the initiation of the process. Very early in the experiment, namely, within fifteen or twenty minutes, as Welch has shown (Trans. Path. Soc. of Phila., xiii., 1887), leucocytes make their appearance in considerable numbers, and must now be regarded as taking an important part in the process. The leucocytes are chiefly of the polynuclear variety, and tend to accumulate at the edge of the clumps of platelets and to some extent between them. As soon as this takes place fibrils of fibrin are formed in close relationship to the white cells, while they are absent near the conglutinated platelets. Sooner or later, the period varying in different cases, a plug is formed consisting of platelets, leucocytes, and fibrin, in which a number of red cells are entangled, reproducing with great accuracy the appearance of the thrombi found in the human subject. No doubt all thrombi do not develop in this way, for there are some, notably the white mural thrombi, that are chiefly composed of white cells, as are those found in the small vessels of an acutely inflamed area. In the latter case the leucocytes are attracted by chemotaxis, and the whole process is obviously inflammatory.

As the white thrombus increases in size it gradually encroaches upon the axial stream, with the result that red cells become entangled in it and a mixed thrombus is produced. A somewhat similar result is brought about by alternating slow and rapid coagulation of the blood, such as occurs in aneurismal sacs, where the clots are commonly found to be laminated, or where the thrombi contract and leave crannies into which the red cells may penetrate. When occlusion of the vessel has taken place, a red thrombus may be superadded upon the white or mixed one (secondary or propagated thrombus).

A thrombus in its early stage, when simply attached to one side of a vessel wall, is called a *parietal* or *mural thrombus;* but when by continuous accretion it has filled up the entire lumen of the vessel, it is called an *occluding* or *obstructing thrombus.*

THE FATE OF THROMBI.—The thrombus in its original situation is called a *primary* or *autochthonous thrombus*, but it is quite a common event for the process to spread until a considerable section of the vascular district is involved—*secondary thrombosis*. As a rule, thrombi grow in length in the direction of the blood stream, but exceptions occur. The advancing end has usually the shape of a flattened blunt cone, and the process extends as far as the next lateral branch. The appearances produced in an advancing thrombus are very striking. The primary thrombus is white or mixed, while the secondary thrombus is red. The secondary thrombus extends along the vessel to the nearest collateral branch, where it comes into contact with the circulating blood, with the result that a white thrombus is formed. This in turn grows until the mouth of the collateral vessel is occluded and a red clot is again formed, and so on almost indefinitely. In this way the circulation may be gravely interfered with over large areas.

Small thrombi may be absorbed and disappear, but the larger ones, provided the patient live, undergo various interesting transformations. Within a very few days of the formation of the thrombus notable changes set in, of which may be mentioned hyaline-granular transformation, organization, simple softening, and puriform liquefaction.

The *hyaline-granular transformation* is marked by the disintegration of the red and white cells. The hæmoglobin is dissolved out, diffuses itself among the fibrin, and is deposited or metamorphosed in various ways. The cells, fibrin, and platelets become finally a granular mass in which the granules become increasingly fine and are eventually fused into a homogeneous, translucent, hyaline-looking material. The chromatin of the leucocytes is liberated, and the thrombus shrinks, becomes more solid, and often assumes a reddish or reddish-brown color. Old thrombi not infrequently become fissured and fragmented, so that fresh reddish clot is deposited in the interstices. In the peripheral portions, too, inflammatory leucocytes and wandering cells from the vasa vasorum may be observed. By this method the thrombus may become so reduced in size that the lumen of the vessel may be reopened and, if these changes occur in an area upon which an operation has recently been performed, secondary hemorrhage may result. As a rule, the thrombus remains firmly attached to the vessel wall, but occasionally it breaks loose and forms an embolus with its ordinary results.

In cases in which the thrombus is bland and not infected it becomes organized into connective tissue. Starting at the place where the clot adheres to the vessel wall a thin layer of endothelium, derived from the lining of the intima of the unaffected parts near by, extends over the surface of the thrombus. Underneath this investment a zone of connective tissue is developed, apparently due to the proliferation of these endothelial cells. The endothelial cells divide and the newly formed cells invade the substance of the thrombus and secrete an intercellular substance. Synchronously with this process the thrombus becomes vascularized from the vasa vasorum and also from the endothelial investment. Fibrous tissue cells are carried in along with the capillaries and form an adventitia to them. The new-formed connective tissue, according to Thoma ("Text-book," vol. i., Eng. trans., p. 285, 1896), is thus a product of the vessel walls. In time the newly formed channels, derived from the endothelial lining on the one hand and the vasa vasorum on the other, meet and vascularization is complete. The portion of the original thrombus between the capillaries is gradually absorbed and the whole mass becomes transformed into a fibrous plug, which undergoes cicatricial contraction. In some cases, as a result of this process, only a few traces are left of the original thrombus in the form of small nodular thickenings of the vessel wall or a few delicate bands traversing the vessel. Not infrequently, however, absorption is not so complete, and new vascular channels are tunnelled through the thrombus. These become lined with endothelium and thus restore more or less completely the integrity of the circulation—the so-called "canalization" of the thrombus.

In *simple softening* the thrombus is converted into a pulpy dirty looking mass. This probably results from the action of unorganized ferments contained in the clot; but it is not always possible in these cases to exclude the action of micro-organisms. Simple liquefactive necrosis is particularly well seen in the case of the "ball thrombi" of the heart cavities, where central softening is occasionally found. Such softening may result in the formation of something like a cyst. The soft material is composed of the degenerated and granular components of the clot, and has a creamy-whitish or grayish-yellow appearance, not unlike pus, whence it has been called by some puriform softening.

Septic softening is usually found in cases of thrombophlebitis, and is a true suppuration of the clot due to the action of pyogenic micro-organisms, among which the streptococcus is a common offender.

Putrid liquefaction is due to the presence of putrefactive germs, and in this case the clot assumes a dirty brown or green color and emits a foul odor. The softening of septic thrombi and the subsequent dissemination of the infected products in the general blood stream is one of the common causes of systemic septicopyæmia.

Many thrombi undergo calcification. This is found commonly in the prostatic plexus, the broad ligaments, and in the spleen, in which localities there are formed small spherical concretions which lie loosely in the vessel. When present in the veins they are called *phleboliths*; when in the arteries, *arteriolitls*.

Localization of Thrombi.—Thrombi may be formed in any part of the vascular or the lymphatic system. Consequently we may conveniently divide them into *cardiac*, *arterial*, *capillary*, *venous*, and *lymphatic thrombi*.

The site of election of thrombosis is in the medium-sized veins where the various anatomical and mechanical peculiarities before referred to, viz., a slow blood current, eddies, and counter-eddies in the stream, obstructions and dilatations, are found in the greatest perfection. Here such questions as the length and obliquity of the venous channels, the presence of valves, the fixation of the vessel walls to fascia, the flow of the blood from a smaller into a larger cavity, play an important rôle. Marantic thrombi are apt to be formed in the veins, particularly of the extremities, and in the large venous sinuses, while those due to infection and angiosclerosis are commonly in the arteries. Numerous exceptions to this generalization, however, might be cited.

Clinically speaking, the most frequent points for the development of thrombi are the vessels of the extremities, especially the lower, the cerebral arteries and sinuses, the portal vein, the inferior vena cava, and occasionally the renal and mesenteric vessels. Many conditions of extensive thrombosis, however, lead to no clinical symptoms, and the presence of thrombi may not even be suspected. Consequently a study of the subject from a post-mortem point of view reveals a somewhat different state of affairs. In this case intracardiac thrombi, and next to these the mesenteric, iliac, and cerebral, are more in evidence.

Leaving out of account post-mortem clots, which are not to be classed with the true thrombi, and cases of acute endocarditis, I have made an analysis of the fatal cases that have occurred at the Royal Victoria Hospital, Montreal, in 688 autopsies of which I have notes. Thrombosis occurred 66 times, or in nearly 10 per cent. of the cases. These were localized as follows: Intracardiac 16, mesenteric 9, aneurismal 8, common iliac veins 7, cerebral arteries 6, inferior vena cava 5, ovarian veins 4, portal 3, splenic vein 3, meningeal, left axillary vein, crural veins, coronary arteries, 2 examples of each; the aorta, pulmonary artery, popliteal vein, brachial vein, pelvic and omental veins, once each. In many cases, however, the thrombi were diffuse or multiple.

We may say in general terms that thrombosis in the arteries is due, in the vast majority of cases, to disease of their walls, usually sclerosis, while that in veins is brought about by inflammation, pressure, or marasmus.

Cardiac Thrombi.—Care should be taken not to confound the soft clots so commonly found at autopsies with true thrombi. These clots are merely coagula identical in origin and structure with the clots that form in blood withdrawn from the body. It is usually taught that they are produced during the death agony, but according to Welch they are more probably formed after death. In diseases, such as lobar pneumonia and acute rheumatism, in which the fibrin content of the blood is high, they are often very abundant, and of a soft gelatinous and often oily appearance.

Intracardiac thrombi are apt to be found in chronic diseases of the heart or its valves, and of the lungs, arteries, and kidneys. The chief factors here are sclerosis of the valves or heart wall, myomalacia, and dilatation of the cavities. Changes in the composition of the blood and the influence of toxins do not play so important a rôle as in the case of the peripheral thromboses. Good examples of intracardiac thromboses, although not usually classed as such, are the vegetations in acute endocarditis. The verrucæ are nothing more nor less than small granulations capped with fibrin, leucocytes, and blood platelets. A very common site for intracardiac thrombi is in the auricular appendages and between the columnæ carneæ, where they may be rather firmly attached. They may also be found upon the surface of the valves. Mural thrombi are usually attached to some area of degeneration of the heart wall, such as is produced by atheroma, infarct, partial aneurisms, and gummata. The commonest form of intracardiac thrombi is the globular, which are usually multiple, and vary in size from that of a pea to an egg; they are sessile or pedunculated. The surface is smooth or again finely lined or ribbed. The interior is frequently converted into a grayish or grayish-brown detritus, or may present puriform softening. The curious rib-like markings found on intracardiac thrombi have attracted the attention of numerous writers, and were referred to by Bristowe as far back as 1855. The appearance has been attributed to wave-like or oscillatory movements in the blood.

A striking and interesting form, to which more than a passing glance should be directed, is the so-called "ball-thrombus." It is found invariably in the left auricle, and in association generally with mitral stenosis. According to Welch a true ball-thrombus presents the following characteristics: (1) Entire absence of attachment, and consequently free mobility. (2) Imprisonment within the cavity in which it is found. (3) Such consistence and shape that the thrombus must not of necessity lodge as an embolus in the ostium just ahead of it. Ball-thrombi vary in size from that of a walnut to a hen's egg and are usually spherical or ovoid in shape. They commonly show central softening, but organization has never been proved to occur. With regard to the clinical effects of such a condition, Wickham Legg has expressed the view (Trans. Path. Soc. Lond., 1878, xxix.) that "a loose thrombus in the left auricle would at any time be ready to act as a ball valve and stop the circulation in the mitral orifice." Contrary to what one would expect this is distinctly a rare event, although it has occurred, as in a case reported by Welch from Osler's clinic. Besides ball-thrombi pedunculated polyps of the heart wall have been described. Some of these are only organized or partially organized thrombi, while others resemble not a little fibromata and myxomata. Some, according to Bostroem, are thrombosed varices or local areas of hemorrhage. Ewart and Rolleston have recorded a case in which a pedunculated thrombus, arising from the fossa ovalis, passed through the mitral orifice and gave rise to the clinical signs of stenosis (Clinical Soc. Trans., vol. xxx.).

Arterial Thrombi.—Here the common causes are disease of the vessel wall or the lodgment of an embolus. Thus sclerosis of the vessel, particularly if associated with a solution of the continuity of the intima, frequently gives rise to the condition. Proliferating endarteritis, as von Manteuffel has shown, is often accompanied by an organizing thrombosis that in time leads to complete occlusion of the vessel.

The most frequent site for arterial thrombosis is, in my experience, in the arteries of the brain; but it is also often met with in the lower extremities, the coronary arteries, the mesenterics, and the aorta and its main branches. Arterial thrombi are to blame for a certain proportion of the cases of gangrene of the extremities. Apart from arteriosclerosis cases of arterial thrombosis are undoubtedly to be referred to inflammation of the vessel walls, a true arteritis. Probably of this nature are the cases sometimes met with in infective diseases like typhoid, typhus, scarlatina, pneumonia, endocarditis, septicæmia, smallpox, and tuberculosis. Nevertheless, it must be admitted that primary arterial thrombosis is to be met with in certain infective, cachectic, and anæmic states in the absence of gross disease of the vessel walls. It is, moreover, not always easy to exclude the possibility that some at least of the cases regarded as primary thrombosis are secondary to a previously occurring embolism.

Thrombosis of the pulmonary artery is believed by Welch not to be particularly uncommon, although cases of obstruction of this vessel have almost invariably been attributed to embolism. It is not unlikely that embolism of the smaller branches at least may be further complicated by thrombosis.

Of more importance is thrombosis of the coronaries of the heart, which is a condition that should be looked for in all cases of sudden death. It is usually due to sclerosis of the vessel or to atheroma of the aorta, aortitis, or to vegetations on the aortic valves; in fact, to any affection that causes obstruction in the vessel. The smaller branches of the coronary arteries are terminal or end arteries, and occlusion of these leads to marked changes in the heart wall, of the nature of infarction or coagulation necrosis. For this condition the term "myomalacia cordis" has been proposed by Ziegler. Provided the patient live long enough, reactive inflammation sets in, the patch softens, and there may be produced a local aneurism of the heart wall, an abscess or even rupture. It is common to find a thrombus on the endocardium of the affected region and sometimes also pericarditis. In some cases healing takes place with the formation of a fibrous scar.

The anastomoses between the main trunks of the coronaries are, however, more complete than has been usually taught, although in fact they are not always sufficient to restore the circulation where it has been suddenly interfered with. I have met with a case in which the orifice of the anterior coronary was completely occluded by sclerosis without the usual consequences of the condition, owing to a free communication with the posterior vessel at the apex of the heart.

Capillary Thrombi.—These are commonly of the fibrinous or hyaline variety, and are as a rule associated with necrosis or gangrene of the tissues. They are met with in the lungs in pneumonia and in hemorrhagic infarcts. In systemic toxæmia and infection they are to be found in the kidneys, the liver, and the lungs, and have also been described in the liver in cases of eclampsia, where they give rise to ischæmic infarcts and necrosis. They have also been described in connection with frost-bite and ergotism.

Venous Thrombi.—The most common site for thrombosis is in the veins. This is accounted for largely on the ground of certain anatomical and functional peculiarities. Chief among these may be mentioned the low blood pressure, the slow stream, the increased carbonic-acid content of the blood, and the presence of valves. While, as has been pointed out by Lancereaux, thrombosis is more liable to occur at regions where there is stasis of blood, this is not in all cases an entirely satisfactory explanation. It is more likely that von Recklinghausen's opinion, before referred to, is correct, viz., that a main factor is eddies in the blood (*Wirbelbewegungen*). These are specially liable to occur where the blood passes out from a small channel into a relatively larger one. In many cases local conditions play a part, as phlebitis, phlebosclerosis, varix, trauma, and compression.

In general, it may be said that venous thrombosis due to sepsis begins in the finer radicles, being produced in the first instance by a local inflammatory infiltration, while the so-called marantic thrombi are more common in the sinuses and medium sized veins. An important feature in this connection is, that once they start, throm bi tend to spread centripetally into the larger vessels. Thus, with the few exceptions due to pressure, thrombosis of the portal vein and the inferior vena cava is brought about by extension from the mesenteric and iliac veins. Local thrombosis in such large vessels as the portal vein and inferior cava is as a rule due to the pressure of enlarged glands or new growths. Two cases of this kind, occurring in my series, were due, the one to a secondary retroperitoneal carcinoma, the other to a new growth in the diaphragm compressing the vessel just outside the heart. One interesting case of local portal thrombophlebitis was due to the presence of an abscess at the hilus of the liver originating in a septic cholecystitis. It is by no means unknown, however, for a thrombus to propagate itself in a peripheral direction in opposition to the blood stream. An example of this was seen in one of my series where a thrombophlebitis of the mesenteric and portal veins extended into the splenic. In view of this fact it is not always easy to determine the exact spot at which a thrombus originated. Careful study of the appearance of the thrombus will, however, in some cases reveal the truth. Thus, the autochthonous portion of the thrombus is firmer, often granular, and adherent, of grayish or grayish-red color, while the propagated thrombus is soft, red, and somewhat loosely attached. A curious fact also is that an occluding thrombus may cause such disturbance of the blood stream that multiple discontinuous coagula are found in the neighborhood of the original one, or these may be connected by red or mixed thrombi. In some few cases also, as shown by my series, multiple primary thrombi may be produced in parts of the venous system utterly remote one from the other, and having no anatomical or functional relationship. In such cases we must assume that there is a systemic disturbance at the back of the condition.

Common sites for primary venous thrombi are in the mesenteric, crural, prostatic, and ovarian veins.

Thrombosis of the mesenteric veins is practically always due to some inflammatory lesion of the intestines, such as appendicitis or colitis and is really a thrombophlebitis. In some few cases it has been due to cachexia or marasmus, and without lesion of the intestine. Curiously enough it is distinctly rare in typhoid fever, which seems to have a predilection for the crural veins, although it has occasionally been met with.

The majority of cases are associated with perforative appendicitis, and here it is the superior mesenteric vessel that is first and chiefly affected, a fact that is readily explained by the position of this vessel which leads directly from the ileo-cæcal angle. The complication is important as it frequently leads to necroses and abscesses in the liver. In such cases the portal vein, although not invariably, is thrombosed as well. The converse has occasionally been observed, viz., that a portal thrombosis has extended into the mesenteric vessels.

Thrombosis of the crural veins, involving not infrequently the iliacs as well, is encountered in tuberculosis, carcinoma, the various cachexias, but more especially in phlebitis of the puerperium, chlorosis, typhoid, and other infective diseases. Many of the cases are associated with marasmus, but it is hard to exclude a local infective cause. The affection is more common on the left side, owing, as has been supposed, to the greater length and obliquity of the left common iliac vein and its passage under the right common iliac artery. As is well known, the condition is not uncommon in typhoid fever during the later stages. There has come under my notice a curious instance where a man had suffered from an attack of typhoid some fifteen or twenty years previously, and had experienced, during this attack, a swelling of the left leg. He contracted a second attack of fever, from which he died, and in this attack, there was again evidence of thrombosis in the same limb. At autopsy there was found a canalized fibrous cord in the crural vein representing the former lesion, while the vessel was completely obstructed by a recent clot which had formed just above the old thrombus.

Portal thrombosis is commonly secondary to thrombosis of the mesenteric or splenic veins. When primary, it is usually due to pressure, as from cirrhosis, syphilis, tumors of the liver, enlarged glands, gall stones, abscesses, chronic peritonitis, or disease of the vessel walls.

Thrombosis of the splenic vein may be brought about by infarcts or abscesses within the organ or by the extension of morbid processes from the pancreas. It is one of the rarest complications of typhoid fever (Köster).

Thrombosis of the inferior vena cava is occasionally met with. When autochthonous it is commonly due to the pressure of a new growth. Three instances have come under my notice at autopsy. In two it was to be attributed to the pressure of a secondary retroperitoneal carcinoma, and in one of these it was propagated from the iliacs. In the third there was a tumor, the size of an orange, in the diaphragm that led to occlusion of the vessel just before it entered the heart.

Thrombosis of the renal veins is rather common in children with cerebral disease or marasmus, but is also met with in adults in chronic nephritis and in malignant growths of the kidney.

Thrombosis of the superior vena cava has been observed a number of times. It is nearly always due to the pressure of mediastinal tumors, aneurisms, or enlarged glands.

Thrombosis of the innominate, subclavian, and jugular veins is usually due to pressure, to cardiac disease, and rarely to infection, empyema, acute rheumatism, tuberculosis, traumatism, and marasmus

Thrombophlebitis of the veins of the broad ligaments is common in septic endometritis. It must in many cases be a rather mild affection and often recovered from, at least if the presence of phleboliths in this situation is any proof.

Thrombosis of the pulmonary veins is secondary to some affection of the lung, such as tuberculosis, abscess, gangrene, tumors, infarction, and pneumonia. It may on occasion lead to embolism in the arterial system.

A rare form of thrombosis, and one chiefly of pathological interest, is that occurring in the adrenal vein, as in a case recently recorded by Woolley from the Montreal General Hospital (*Jour. Med. Res.*, March, 1902, p. 231). It was found in a child of eleven months that had suffered from measles, and led to infarction of the organ.

The Results of Thrombosis.—The morbid changes and symptoms produced by thrombosis are attributable, in the first place, to the obstruction of the circulation due to the clot, and, secondly, to the special character of that clot and the condition of the vessel wall. Much depends upon the position of the occluding plug, the rapidity and extent of the obstruction, the formation and the effectiveness of the collateral circulation, the nature of the thrombus, and the local and systemic peculiarities. Obstruction of arteries, particularly when of the terminal variety, is more likely to be followed by marked results than is obstruction of veins, where the anastomoses are as a rule much more abundant. If the collateral circulation be quickly established, no pathological or clinical effects are produced and *restitutio ad integrum* may be complete. When the condition sets in gradually, the symptoms are slow in developing, but frequently increase in intensity. In parts unfavorably constituted the symptoms are acute and the results serious. Obstruction of arteries leads often to necrosis and softening; that of veins to congestion and œdema, followed also, it may be, by gangrene or necrosis. Should infective micro-organisms be present, a local abscess, or even systemic infection, may occur.

With regard to the clinical signs, everything depends on the localization of the thrombus. Should it occur in some vital organ, like the heart, death may occur immediately or very soon. Should it affect important districts, like the cerebral cortex or internal capsule, peripheral palsies result that direct the attention to the position of the lesion. Or, again, localized œdema or the dilatation of superficial vessels will suggest its presence. While it is true that many thromboses occur in what may be called "blind" regions, those of important vessels, such as the cerebral arteries and sinuses, the crural veins, the portal vein, and the inferior vena cava give rise to fairly characteristic signs which render them amenable to ordinary methods of diagnosis. The effects differ considerably according to the part of the circulatory system involved.

The presence of intracardiac thrombi may at times perhaps be suspected, but can rarely if ever be diagnosed with certainty. Except for providing emboli, the globular thrombi can hardly produce any definite symptoms. The presence of thrombi in or near the various ostia of the heart may occasion murmurs and thrills identical with those resulting from valvular disease. Unless, however, the orifices are encroached upon, few or no symptoms are produced that will suggest the presence of thrombi. Even in the case of "ball thrombi" the signs are indistinguishable from those of mitral stenosis, and sudden death is rare, contrary to what one would expect.

The clinical manifestations of arterial thrombosis are in many cases indistinguishable from those of embolism. Where the circulation is cut off slowly a collateral anastomosis may be established, even in the cases of the main trunks like the femorals, iliacs, and aorta, and the results may be trivial. Should, however, the occlusion be brought about suddenly, as not infrequently happens, particularly in the case of organs like the brain, spleen, and kidneys, where many of the arteries are "terminal" or end arteries, the consequences may be serious. Furthermore, the possibility of a collateral circulation being established depends largely upon the condition of the vessel walls and the vigor of the systemic circulation. The differential diagnosis between arterial thrombosis and embolism is beset with difficulties. The most important points are the sudden onset in embolism and some condition of the heart or vessels which could give rise to embolism. Mistakes, however, readily occur.

In the case of thrombosis of the arteries of an extremity, as for instance the leg, the first symptom is pain, which is often agonizing and paroxysmal. The limb becomes pale, cold, mottled with livid patches, numb, and paretic. Tactile sensibility is lost, although there may be increased susceptibility to painful impressions. The limb becomes œdematous and the skin moist. Should the collateral circulation not be established gangrene sets in, usually of the dry variety, unless the veins also become blocked or the limb become infected. This form is often due to arteriosclerosis and is met with in diabetes.

Charcot's syndrome, "intermittent claudication," has been observed in cases of thrombosis of the femoral and iliac arteries, and the abdominal aorta. It is more common, however, in simple arteriosclerosis. In this condition the lower extremities during rest receive enough blood for their needs, but not during active exercise. Consequently after exercise some muscular weakness and numbness of the limb may be observed, and in the severer cases the symptoms are very pronounced, with the addition of pain and cramps in the leg, which becomes cold, pallid, and sometimes cyanosed. After a short rest the symptoms disappear, only to reappear on occasion.

Thrombosis of the pulmonary artery may be entirely latent, or again may cause rapid or immediate death. In some cases the affection is subacute or chronic, and is characterized by dyspnœa, cyanosis, incompetency of the heart, and hæmoptysis.

Thrombosis of the coronary arteries of the heart is not uncommon, and is a more frequent cause of infarction of the heart than is embolism. Sudden death may result, but, when the patient lives, symptoms practically identical with those of fibroid degeneration of the myocardium may be produced. These are a slow irregular pulse, dyspnœa, precordial distress, and anginal attacks.

Thrombosis of the cerebral arteries leads to ischæmic softening with all its consequences—loss of consciousness, hemiplegia, mental degradation, and the like.

Capillary thrombosis, owing to the free anastomotic communications, does not give rise to symptoms unless large areas are involved. Necrosis is the common result but it is probably more usual for this to be a cause of thrombosis than the reverse. The association of these thromboses with burns, frost-bite, ergotism, and various infections has been before referred to. Welch has observed the condition in the bases of gastric ulcers.

The most frequent examples of thrombosis are afforded by the venous system, for reasons that have already been sufficiently entered into. The venous anastomoses are, however, so abundant in most parts of the body that the most extensive vascular occlusion may occur without the production of serious consequences. Much depends on the localization of the clot and the rapidity of its formation. The varying and often apparently contradictory results produced by venous thrombosis are to be explained, however, not entirely on these grounds, but by a reference to other factors, such as anæmia, cachexia, and infection. Phlebosclerosis and phlebitis also play a part. As we meet it in, say, the extremities, the most constant and characteristic symptom of venous obstruction is œdema, sometimes (although by no means invariably) combined with hemorrhage. In the case of the cerebral, splenic, and mesenteric veins necrosis may occur. This event is excessively rare in the case of the extremities. In addition to the mechanical effects should be mentioned inflammation, which is often secondary to the thrombotic process, or indeed may be the cause of it, as in the case of phlebitis. This often leads to active hyperæmia, pain, and constitutional disturbance.

The most familiar example of venous thrombosis is that which occurs in the extremities, usually the lower. The affection may be unsuspected or give rise only to trifling signs, such as slight œdema of the limb. In other cases there may be pain as well, sometimes with a little fever (phlegmasia alba dolens), or again there may be chills and high fever with even evidences of septicopyæmia. Some observers (Mahler, Wyder, and Singer) have called attention to the increased rapidity of the pulse, which may even be present before actual thrombosis takes place, and may persist after the temperature has fallen. In a typical case the affected limb is swollen, there is more or less pain, usually more severe in the groin, the inside of the thigh, the popliteal space, and the calf. There may be sensations of numbness or tingling. The limb becomes swollen and firm, the skin is tense and white, often showing distended veins, and the tissues are hard and elastic. In other cases the skin is livid and congested. More or less phlebitis commonly results. The great danger of thrombosis of the veins of the lower extremities is in detachment of the clot and fatal pulmonary embolism. This is by no means an infrequent termination. It is perhaps more common in puerperal and septic cases. In cases that recover the limb may remain swollen for many months. Necrosis of the part only exceptionally occurs, and is due probably to some arterial complication. Pain and other nervous phenomena in some cases have led to the recognition of a neuralgic type of the affection (Graves, Trousseau, and Quenu). A mild peripheral neuritis has also been observed. Rare sequels of crural thrombosis are varicose veins, ulcers, elephantiasis, hypertrophy or atrophy of muscle, and club-foot.

Unless due to some continually acting cause, such as an intrathoracic tumor or aneurism, thrombosis of the arms is a less severe affection than that of the lower extremities.

Thrombosis of the inferior vena cava is an affection of some importance, and is in my experience frequently overlooked. It may occur without any special symptoms, but when present they are usually characteristic. In the cases that I have seen the thrombosis frequently began in one leg and was followed by thrombosis of the other. Later, there was more or less abdominal pain with extension of the œdema to the abdominal and lower thoracic wall. In one case the œdema was extreme, and curiously localized to that part of the body which is below the breasts, at which level the line of demarcation was sharply defined. The most important sign, however, is the presence of distended veins in the abdominal and lower thoracic walls. The veins are sometimes tortuous and varicose, and may reach the size of the little finger. The anastomosis is performed by the superior and inferior superficial epigastric, the long thoracic, the superficial circumflex iliac, the external pudic, the lumbo-vertebral anastomotic trunk of Braune, and various other veins. There is also communication through the visceral veins and the azygos. When the anastomosis is chiefly through the deep vessels to the exclusion of the superficial ones, the diagnosis becomes much more difficult, if not indeed impossible. Should occlusion of the renal veins occur as well, hæmaturia and albuminuria may be present, yet these are more often absent than present. The diagnosis is rendered still more probable when one is able to determine the presence of retroperitoneal new growths in the upper part of the abdomen or of tumors at the hilus of the liver. Schlesinger (*Deutsche med. Woch.*, S 460, 1896) has pointed out that in a few cases the obstruction is in one leg only. This may be due to the existence of a collateral circulation on one side due to a former iliac thrombosis; to complete occlusion of the iliac on one side with a parietal thrombosis of the inferior cava; or to congenital duplication of the cava.

Thrombosis of the portal vein is perhaps more commonly of the septic variety (portal pylephlebitis). This is one of the common accompaniments of abscesses of the liver. The affection as a rule extends from the mesenteric vessels and is not uncommon in appendicitis. Simple portal thrombosis when it develops gradually is hardly to be diagnosed. When present the symptoms are those of portal obstruction, viz., ascites, hæmatemesis, enlargement of the spleen, dilatation of the superficial abdominal veins, and progressive emaciation. The symptoms may, however, be far from characteristic, or indeed may be absent. In general, however, the acute onset, the intensity of the portal obstruction, and particularly the quick return of the ascites after tapping are very suggestive. These points are of all the more importance when the signs develop in a hitherto healthy person or in the course of some affection not ordinarily associated with portal obstruction.

Thrombosis of the mesenteric veins is usually due to ulceration or other inflammatory lesion of the intestines. It is rather common in appendicitis. As a rule the superior mesenteric vein is first and chiefly affected. The condition is frequently a thrombophlebitis. There may be no symptoms, but generally there are intense abdominal pain, tympanites, vomiting, sometimes bloody, melæna, and collapse.

Thrombosis of the renal veins is comparatively common, especially in children with marasmus. It may extend from the vena cava, but may be primary. Contrary to what one would expect, hæmaturia and albuminuria are rather more often absent than not.

Thrombosis of the splenic vein is rare. It is usually associated with abscess or infarction of the spleen, or disease of the pancreas. In some cases the process spreads in a retrograde manner from the mesenteric and portal veins, as in one of my cases. Welch has met it also in calcification of the splenic vein, and Köster in typhoid. Infarction and necrosis of the organ may result, as in a case arising from torsion of the pedicle, described by Osler.

Obliteration of the superior vena cava is excessively rare as an autochthonous condition. Generally it is due to the pressure of a mediastinal growth enlarged glands, or an aneurism The symptoms, when characterisitic, are cyanosis and œdema of the face, arms, neck, and thorax, and dilatation of the veins over the anterior aspect of the thorax and upper part of the abdomen.

Thrombosis of the pulmonary veins is usually secondary to lesions of the lungs, such as gangrene, tumors, abscess, emphysema, pneumonia, and tuberculosis. It may rarely give rise to emboli in the general arterial system

Thrombosis of the innominate, subclavian, and jugular veins is met with in connection with cardiac disease and compression. Occasionally it is seen in acute rheumatism, tuberculosis, empyema, traumatism, marasmus, and infection. Thrombosis of the jugular frequently originates in thrombosis of the lateral sinus in cases of mastoid suppuration, and may give rise to general infection. The symptoms in the various forms are analogous to those already described.

TREATMENT.—Cases must be treated on their merits. Marasmus, enfeebled circulation, and infection being the important etiological factors, one should endeavor to promote nutrition, to strengthen the heart, and to prevent complicating infection. In the last event, should the focus of infection be accessible, it should be treated on surgical principles. We are, however, unable to control the process of thrombosis directly, so that our further efforts should be directed to assisting the establishment of collateral circulation, in order to minimize the effects of congestion and to prevent gangrene. These measures are, however, only applicable to the affection when it involves the extremities. In the case of venous thrombosis of the lower extremities the *utmost care must be taken to avoid detaching the clot*, on account of the imminent risk to life from pulmonary embolism. Here "masterly inactivity" is the watchword. Absolute rest must be enjoined, suitable diet prescribed, and the limb fixed in a proper position. In the case of the lower extremity the patient should lie on the back, with the limb on an inclined plane. The limb should be wrapped in cotton-wool. If pain be severe, applications of lead and opium should be employed or morphine be given internally. All manipulation and even palpation of the limb should be strictly avoided. Massage is absolutely contraindicated. I have known death to result from this irrational procedure. To insure fixation of the limb plaster of Paris may be applied to the hip. The patient should be confined to bed in an average case for at least six weeks. The danger can hardly be said to be past, however, for two weeks longer. During convalescence gentle bandaging should be adopted or a long stocking worn.

Should gangrene result, the case must be treated on ordinary surgical principles. *Albert George Nicholls.*

THRUSH. See *Mouth, Diseases of*, in THE APPENDIX.

THYMACETIN.—An analgesic, prepared and named by Hoffman, of Leipsic, and brought to the notice of the profession in 1892 at a meeting of the Berlin Association for Psychiatria and Nervous Diseases, by Prof. F. Jolly (*Cent. f. die gesam. Ther.*, February, 1892). It is closely allied to phenacetin, bearing the same relation to thymol that the older drug does to phenol. It occurs as a white crystalline powder, only slightly soluble in water. Professor Jolly described the results of a series of experiments upon animals, with this drug, and its use in a number of cases of nervous and mental diseases. He did not find that it had any antipyretic action, but its analgesic and hypnotic properties were undoubted. He found it of most service in headaches and pain of a purely nervous character, but when there was any organic disease it failed to produce any beneficial effects. He considered its action equal to that of phenacetin. As an hypnotic it was administered with success. The dose ranged from three and three-quarters to fifteen grains. No toxic action was noticed, but it produced an acceleration of the pulse and a complaint, in some cases, of a fulness, beating, and noises in the head. *Beaumont Small.*

THYME or **GARDEN THYME.**—(*Herba Thymi*, P. G.; *Thym*, Cod. Med.). The dried herb of *Thymus vulgaris* L. (fam. *Labiatæ*).

The common garden thyme is a low, slender, more or less hairy, much-branched shrub, a foot or less high, with brown, nearly cylindrical branches, minute, opposite, narrowly oval or lanceolate leaves, and blunt, interrupted, spike-like clusters of violet-colored flowers terminating the branches. Flowers small. Calyx and corolla both labiate. Stamens four, sometimes short and equal, at other times long, exserted, and in pairs. It is a native of Southern Europe, but cultivated there and elsewhere for centuries.

Thyme has but little history as a medicine, being mostly used as a condiment and flavor for soups, etc. It has, however, far more important medicinal properties than others of its class. Since these are almost wholly due to the volatile oil and its contained thymol, they are considered below in connection with those substances. It contains about two and a half per cent. of volatile oil, with a small amount of tannin and other unimportant constituents. The dose of thyme is 2–4 gm. (gr. xxx.–lx.).

FIG. 4710.—Thymus Vulgaris. Flowering branch, about half natural size. (Baillon.)

Oil of Thyme (*Oleum Thymi*, U. S. P.) is thus described by the Pharmacopœia.

"A yellowish or yellowish-red liquid, having a strong odor of thyme, and an aromatic, pungent, afterward cooling taste. It becomes darker and thicker by age and exposure to the air.

"Specific gravity: 0.900 to 0.930 at 15° C. (59° F.).

"It does not fulminate with iodine.

"The oil is soluble in half its volume of alcohol, forming a clear solution which is neutral or only very slightly acid to litmus paper. The oil is also soluble, in all proportions, in carbon disulphide, and in glacial acetic acid.

"With a drop of ferric chloride T.S. the oil yields a greenish-brownish color, which changes to reddish.

"If 1 c.c. of the oil be shaken with 10 c.c. of hot water, and, after cooling, the liquid be passed through a wet filter, the filtrate should not assume, with a drop of ferric chloride T.S., a bluish or violet color (absence of *carbolic acid*)."

The oil thus described is what is known commercially as the *brown* or *red oil*, besides which there is a *white oil*. The latter was formerly described by the Pharmacopœia, but is, as a matter of fact, medicinally inferior to the former, though it is preferred for those purposes in which absence of color is an object. The commercial oil varies most widely in its characteristics, even when genuine, and the official description should be carefully observed. Although oil of thyme is of complex composition, its properties are essentially those of its thymol, of which the amount should be from twenty to twenty-five per cent. Occasionally a larger or smaller part of this is naturally substituted by carvacrol. *Cymene* and *thymene* are also present. The dose of the oil is one to five, or even ten minims.

Thymol ($C_{10}H_{14}O$) is also official, and is defined as "a phenol occurring in the volatile oils of *Thymus vulgaris* L., *Monarda punctata* L., and *Carum Ajowan* (Roxb.) B. et H., and is thus described:

"Large, colorless, translucent crystals of the hexagonal system, having an aromatic, thyme-like odor, and a pungent, aromatic taste, with a very slight caustic effect upon the lips.

"Its specific gravity, as a solid, is 1.069 at 15° C. (59° F.), but when liquefied by fusion it is lighter than water. It melts at 50° to 51° C. (122° to 123.8° F.), remaining liquid at considerably lower temperatures. When triturated with about equal quantities of camphor, menthol, or chloral, it liquefies.

"Soluble in about 1,200 parts of water at 15° C. (59° F.), and in less than its own weight of alcohol, ether, or chloroform; also readily soluble in carbon disulphide, glacial acetic acid, and in fixed or volatile oils.

"Its alcoholic solution is optically inactive.

"If a very small crystal of thymol be dissolved in 1 c.c. of glacial acetic acid, and then six drops of sulphuric acid and one drop of nitric acid be added, the liquid will assume a deep bluish-green color.

"If 1 gm. of thymol be heated in a test tube, in a water-bath, with 5 c.c. of a ten per cent. solution of sodium hydrate, a clear, colorless, or very slightly reddish solution should be formed, which becomes darker on standing, but without the separation of oily drops (absence of *thymene*, or lævogyrate *pinene*, $C_{10}H_{16}$). If to this solution a few drops of chloroform be added, and the mixture agitated, a violet color will be produced.

"When a crystal of thymol is heated in an open capsule, or in a watch glass, on a water bath, it should gradually volatilize, leaving no residue (absence of *paraffin*, *spermaceti*, etc.)."

Thymol, besides its important properties as a carminative and intestinal and general stimulant, shared by the volatile oils of the *Labiatæ* in general, is one of the most useful antiseptics which we possess. It is of the greatest service both for its application to the outer surface of the body and to all mucous surfaces, and especially in purulent and other septic catarrhal disorders, and as an intestinal disinfectant. Its value for the latter use depends upon the energy and permanence of its effects, it being superior in these respects to carbolic acid, yet possessed of but very slight poisonous properties, large doses being required for the production of poisonous effects. It is the principal active constituent of "listerine," with which the *Liquor Thymoli Compositus*, or *Antiseptic Solution*, is practically identical. The dose of thymol is one to five grains. An ointment of thymol, strength five per cent., is frequently of great value in relieving itching.

Henry H. Rusby.

THYME, WILD, or *Serpyllum*, is the herb *Thymus Serpyllum* L., native of the Old World and sparingly naturalized in the United States. The stems are much more slender even than those of garden thyme, partly prostrate, and usually reddish and pubescent. The leaves are shortly petioled, opposite, scarcely one-fourth of an inch in length, and about half as broad, ovate, the flowers small, pale, and darker-spotted. Its odor and taste are similar to those of garden thyme, and it contains a volatile oil practically identical with that of oil of thyme, with which its properties agree.

Henry H. Rusby.

THYMOFORM is a yellowish, tasteless powder composed of formaldehyde and thymol and smelling feebly of the latter. It is insoluble in water, mineral oils, or glycerin, but dissolves in alcohol, ether, chloroform, and olive oil. It is an antiseptic dusting powder.

W. A. Bastedo.

THYMOL CARBONATE AND THYMOL-URETHANE. See *Thymotal*.

THYMOL CHLOR-METHYL-SALICYLATE is a white crystalline powder which is insoluble in water, but is soluble in alcohol, ether, acetic ether, and in dilute solutions of the alkalies. It is used as an antiseptic.

W. A. Bastedo.

THYMOTAL.—Tyratol, thymol carbonate—is prepared by passing phosgene gas ($COCl_2$) through a twenty-per-cent. solution of sodium hydroxide in which thymol is dissolved. It is a white, nearly tasteless crystalline body with a faint thymol odor. It passes through the stomach unchanged, but probably splits up in the intestine. It is employed as an anthelmintic in dose of 0.5–1 gm. (gr. viij.–xv.) for children, and 2 gm. (gr. xxx.) for adults.

Pool, of Dutch Guiana, says it is better than thymol for the anchylostomum duodenale.

Thymol urethane has a similar use and dosage.

W. A. Bastedo.

THYMUS.—INTRODUCTION.—The thymus gland (also known in English as the thymus, or popularly as the neck or throat "sweetbread"; in German as the Thymus, Thymusdrüse, Brustdrüse, Bries or Briesel; in French as thymus) enjoys the unique distinction not only of being a transitory organ of extra-uterine life in man, but also of existing in three or possibly four distinct and different morphological conditions during its life history.

COMPARATIVE ANATOMY.—This organ is not, however, peculiar to man, being present in all vertebrata, including the lampreys (cyclostomata) in which its existence was considered doubtful until recently. Its development does not proceed so far in some of the lower vertebrate animals as in mammals, being often arrested at the epithelial stage as seen in certain fishes where, during life, the thymus is an epithelioid organ, or rather an epithelial, mucus-secreting gland. In other fishes, in reptiles, and in birds it usually attains the condition of a lymphadenoid structure and persists through life, though it may undergo retrograde metamorphoses. In mammals the thymus passes through certain changes leading to its complete transformation into indifferent tissue before adult life is attained, but to this rule there are many exceptions, as one may discover by careful dissection of such animals as the rabbit, guinea-pig, dog, cat, cow, and horse. It is by no means uncommon to find large, well-developed thymus glands apparently quite like the "sweetbread" of the calf or lamb among adult animals of the varieties mentioned. This is the case in man, as we shall see later.

EMBRYOLOGY.—Until comparatively recent years the embryology of the thymus was obscure; but the observations of Renaut, Kölliker, Stieda, Born, Rabl, and Mall have pretty thoroughly established the developmental history of the organ. The generally accepted idea now is that in the higher orders, and probably in all vertebrata, the thymus develops as a paired organ from the third pair of gill clefts, and according to most authorities from the endodermal lining of these clefts, though His first held that the ectoderm furnished the component cells of the thymus anlage, and Kastschenko maintained that both ecto- and endodermal cells participated in forming the primary organ. The anlage of the thymus is a pouch of endoderm forming in the third gill cleft, and in a human embryo of the fifth week His found this pouch open. Originally the thymic pouch communicates with the fore gut or pharynx, but this connection is soon lost and the elongated sac with thickening epithelial walls, first lying transversely across the future neck, becomes free from its moorings to the gill clefts and shifts toward the tail, the larger dorsal end becoming the future head of the organ. The lumen of this cylindrical sac remains open, how long is still unsettled, though the twelfth week in man is the period usually assigned, after which the anlage becomes a solid cord of cells with numerous buds. Thus in its first appearance this organ is similar to a secreting tubular or acinous gland. A shifting of the endodermic anlage continues in the direction of the future thoracic cavity along the vagi and carotid arteries, reaching almost to the heart, finally making the lobes into which the fully formed organ is divided.

But the anlage does not long enjoy a strictly endodermal structure, for blood vessels push in from the mesoderm and soon after round cells, presumably also of mesodermic origin, insinuate themselves into the epithelial cords, while others gather about to form investing masses which soon predominate. As we shall see later, these mesodermic cells form the larger bulk of the fully developed thymus, which, even in the fœtus, attains great size.

The preceding account represents the most widely accepted views relative to the origin of the thymus in man, though such points as the possible participation of other (the fourth) gill clefts and of the ectoderm should be mentioned. In vertebrates below mammals variations are seen, the second gill cleft in the frog, the first four in fishes, and the second, third, and fourth being at times called upon. The questions as to the time of closure of the lumens of the tubules in the anlage and the relation of these tubules to the corpuscles of Hassall (*vide infra*) are still under discussion.

It is at least worthy of passing notice that some similarity exists in the development of the thymus and several organs in its immediate neighborhood, like the tonsils, thyroid, and parathyroids, though the full details regarding their embryology have not been established.

ANATOMY.—The fully formed human thymus makes an organ of considerable size lying in the anterior mediastinum at or near the median line. It generally consists of two broad and flat lobes more or less closely united with vascular connective tissue, and enveloped by a continuous sheath of fascia partly from the deep fascia of the neck and in part a reflection of the cephalic portion of the pericardial sac. As this smooth capsule is stripped from the organ several layers of loose areolar tissue come into evidence, the deeper ones of which send offshoots into the substance of the gland. The cephalic extensions of the thymus bring it almost in touch with the lateral lobes of the thyroid, to which it is united by a cord-like mass of dense connective tissue containing branches of the inferior thyroid artery and some veins. Downward, the thymic lobes reach well upon the pericardium, a distance of two or three finger-breadths, and to the interval between the second and fourth ribs. Its ventral surface is separated from the manubrium sterni by loose areolar tissue. Dorsally, its thoracic portion lies in relation to the arch of the aorta, the aortic branches, and the left innominate vein. The body and edge of the right lobe adjoin the innominate artery, superior vena cava, and right phrenic nerve; while the left lobe comes close to the common carotid artery and left phrenic nerve. Both vagi and the recurrent laryngeal nerves lie well behind the lobes of the thymus, and this is the case with the carotids in the cervical region. Here, also, the continuation of the organ brings it to lie beneath the origin of the sterno-hyoid and sterno-thyroid muscles, and in front of the trachea, everywhere more or less separated by loose connective tissue and fat. Thus it is seen that the thymus lies partly in the neck and partly in the chest, its thoracic portion being the expanded leaflets or lobes, its cervical portion consisting of the narrow finger-like extensions of these lobes. The organ might aptly be compared to two small, rather thin hands in the index attitude, the two fingers lying closely together and pointing upward. As a whole the organ is loosely held in position; it can be easily moved sidewise and lifted somewhat, and, after severing its thyroid connections, it shortens and sinks into the chest.

The blood supply of the organ is derived principally from the mediastinal branches of the internal mammary artery, and from the inferior thyroid. Its dorsal surface, applied to the pericardium, is penetrated by minute branches of the pericardial arteries. All its arteries are comparatively small, thus differing from those feeding the thyroid. On the contrary, the thymic veins are large, making a stem 3 mm. in diameter lying between the lobes and terminating in the left vena innominata (Dwornitschenko).

The lymphatics are numerous and large. They enter the glands of the anterior mediastinum and, according to Astley Cooper, two large vessels proceed, one from each lateral lobe, to open by one or more orifices into the internal jugular vein (Quain's "Elements of Anatomy," tenth edition, vol. ii., pt. ii., p. 556).

When fully exposed by dissection the thymus, in the height of its development, is a soft, smooth, pinkish, or pinkish-gray, bilobed, flattened organ, slightly concave dorsally where it lies against the heart's sac, widest below and tapering above. Because of the penetration of connective-tissue bands into its substance it is mapped out into distinct lobules and sublobules, giving it the "sweetbread"-like appearance, not unlike that shown by the pancreas or the salivary glands. Within the lobules it is often possible to make out distinct rounded or polygonal follicles. A milky juice has been described by the older anatomists as coming from the cut organ especially in young children, or in adults in whom the organ was persistent and enlarged, and this circumstance has recently been alluded to as possibly of pathological significance. Probably, however, this condition is the result of a post-mortem softening; one of the artifacts to which the organ is prone. Of the same nature is the central canal with its lateral branches, or the "central cavity" so persistently mentioned in descriptions of the human thymus even in some present day treatises on anatomy.

At the height of its normal growth the thymus attains a length of 9.5 cm., a width of 5 cm., a thickness of 1 cm., and weighs 20 gm. It sinks in water with a displacement of 21 c.c. But the organ may depart widely from the average standard; it may be larger or smaller. Its relations will vary according to its size, and it may lie to the left or right of the median line. A bridge of true thymic tissue may come in direct contact with the thyroid gland, or 3 or 4 cm. may intervene between the thyroid lobes and the cephalic extensions of the thymus. Sometimes the distinct divisions into lobes may be lost, or one lobe may greatly exceed its fellow in size. Multiple lobes, from three to seven or eight, may at times be found. Small lobes or islets of thymus tissue are sometimes found at a considerable distance from the organ proper, making *accessory thymuses*, as also seen in the case of the spleen and thyroid.

Histology.—The connective-tissue envelope of the active thymus sends offshoots or septa into the gland, dividing the lobes into lobules, and these again into secondary lobules from 4 to 11 mm. in size, finally separating the lobules into smaller, roughly spherical foci of solid thymic tissue termed follicles or acini, from 0.4 to 0.7 mm. in size. Ordinary white fibrous tissue mixed with elastic fibres makes the principal part of the enveloping sheath or capsule surrounding the thymus; in this more or less fat is mixed, depending upon the proportion of adipose tissue in the body at large. In the finer septa isolating the follicles or acini only loose white fibres with delicate elastic fibrils are present (Mall).

The follicles consist throughout of adenoid tissue, giving the impression made by the follicles of the lymph glands, even to the extent of showing a lighter central portion and darker periphery. This resemblance is heightened by the fact that the vast proportion of the elements composing the thymic acini are lymphoid cells. But more careful examination with higher magnifying powers brings out an evident difference between the central portion or medulla, as it is called, and the germinal centre seen in the follicle of lymph nodes. The darker, more solid peripheral portion of the acinus (cortex) is quite similar to the bulk of tissue composing the follicle of a lymph gland.

The cortical and medullary portions of the thymic acini are not sharply circumscribed. In general the reticulum of the medullary substance forms a network or framework of branching cells whose processes communicate with each other and with the walls of the blood-vessels. The nuclei of these radiating cells are 6–8 μ in size and rather poor in chromatin. In the meshes of the network lie small mononuclear leucocytes with nuclei 3–5 μ in diameter (lymphocytes); larger leucocytes with polymorphous nuclei are more seldom present, along with the eosinophilous cells described by Schaffer, which are also found along the blood vessels of the interlobular connective tissue. Multinuclear (giant) cells are also to be found in the medulla, which, according to Watney, are derived in part from the cells of the framework. But, as Schaffer finds, there are also multinuclear cells which are united with the capillaries at the ends of which they are located and with whose retrogression they are related. At certain points the constituent cells of the framework press closely together, making flattened polyhedral objects whose arrangement resembles that of stratified epithelium. Here the extraneous (multinuclear) cells are entirely absent or only sparingly found. These nests or cords of epithelium, deprived of blood-vessels, show, at certain places where they adjoin the connective tissue, a layer of higher cells which resemble those in the basement layer of a stratified epithelium. That the medullary substance of the thymic follicle arose from an epithelial anlage cannot well be doubted from the outspoken epithelial nature of the cells just described, which must be regarded as direct descendants from the anlage. It is more difficult to decide whether the radiating cells of the medullary framework are epithelial in origin. In preparations stained after Van Gieson's method a portion of the medullary framework shows connective-tissue fibres, indicating that a part at least of this network is mesodermic in origin.

Besides the epithelial islets just described one finds in the thymus of advanced embryos, in greater numbers in the fully developed organ, and in the early stages of its retrogression, numerous characteristic objects varying in size and condition. These bodies are known as the concentric or lamellated corpuscles of Ecker, Hassall's corpuscles, or thymic corpuscles. They abound in the medulla exclusively. In the simplest form they are spherical bodies 13–22 μ in diameter, with a central portion feebly refractive, homogeneous, or granular, surrounded by shell-like flattened ep helial cells. The nuclei of the epithelial cells are plainly discernible, or they may be swollen, with their chromatin dispersed or even entirely missing. Here and there between the constituent cells leucocytes appear which may even penetrate to the central mass of the corpuscle. These bodies closely resemble the epithelial cell-nests or pearls seen in epitheliomas. Their nature and origin was long obscure, but the embryological studies of His and Stieda have thrown light on the question, which is not, however, even now definitely settled. According to the authorities just quoted the formation of these bodies is due to the separation of the primary thymic epithelium into isolated portions by the ingress of mesodermic elements, the pressure apparently producing their spherical contour, after which a degeneration of the central cells ensues, though this degeneration does not follow a uniform course. Usually a homogeneous refractive mass appears; at other times refractive granules, droplets, or flakes form. Whether the homogeneous substance is colloid, or not, is undetermined, though the microchemical test of Amman shows the same color-reaction as that given by the colloid of the thyroid gland. The substance is compared to that of prostatic stones by Kölliker. It certainly is a proteid and not a fatty substance, though both fatty and calcareous changes occur in Hassall's corpuscles. Frequently concentric corpuscles are seen in which the nuclei have entirely disappeared and the cell substance has become reticulated; or it undergoes transformation into soft masses which give a mucin reaction.

Along with the simple concentric corpuscles, bodies appear with multiple centres from which the cell layers radiate. Irregular forms, spindle- or club-shaped, or variously bent and knotted, also abound. But in all these corpuscles the concentric disposition of the component parts is retained. These bodies may reach a size of 0.1 mm. It is important not to confuse with these true thymic corpuscles epithelial cell masses devoid of the concentric arrangement, found especially in individuals of advanced age, in which the thymus is well along in its retrogression; they attain a diameter of 0.2–0.3 mm., and may be designated epithelial spherules.

In poorly fixed or macerated specimens the Hassall corpuscles and epithelial spherules readily fall out during preparation; and where several of them have been in contact, a space is left which may easily be mistaken for a central canal. The loss of large epithelial spherules from the medulla may give the impression of considerable cavities here, but these artifacts are not to be confounded with cavities clad with ciliated epithelium, first noticed by Remak, which are of embryonic origin due to imperfect closure of the primitive epithelial canals of the thymic anlage. It is also advisable to have in mind the occasional presence of aberrant parathyroids which may find their way into the medulla of the thoracic portion of the thymus.

The cortical portion of the thymic follicle is characterized by the possession of abundant blood capillaries, and has much similarity with the structure of lymphatic glands. It has a delicate reticulum whose meshes are packed with cells which are for the most part small, mononuclear lymphocytes. In sections stained with nuclear dyes this preponderance of lymphocytes gives the cortex a dark hue, plainly outlining it from the lighter medulla. As to the nature of the reticulum, whether entirely cellular or partly fibrillar, it is a question still undecided, as is the case in reference to the lymph glands. Watney holds that the reticulum is a dual structure, both cellular and fibrillar. It is highly probable, however, that it does not develop from the ectodermic thymic anlage.

In conjunction with the cortical reticulum and lymphoid elements one finds the eosinophilic cells, described by Schaffer and by Sultan, scattered through the whole cortex, especially along the surface and in the neighboring connective tissue. Further, there are peculiar round or branching cells reaching a diameter of 12–30 μ thickly disposed about the capillaries, and containing strongly refractive granules, differing from those of eosinophilic cells, but more closely resembling the colloid-like droplets in the centre of the Hassalian corpuscles because of their insolubility in acids and alkalies. These granules vary in size, the average being 4 μ in diameter; they stain but faintly in eosin and differ from fat by their insolubility in ether. These cells can most readily be demonstrated by treating sections of thymus hardened in alcohol with dilute caustic soda, which clears the tissue, bringing out the granules in the cells that lie along the capillary walls of the cortical portion only.

Of especial importance is the fact pointed out by Schaffer that in smear preparations of the thymus nucleated red blood corpuscles are to be found, as is the case in the spleen and bone marrow. They are hard to find in sections. They are especially abundant in the cortex, though present in the medulla.

As first pointed out by Kölliker, the blood-vessels of the thymus are peculiar. The arteries following the central cords in the interior of the lobules penetrate the follicles and pass into a network of capillaries along the inner side of the cortex. The central portion of the medulla is largely free from capillaries. The branching arterial capillaries at the border of the medulla pass into capillaries which mostly penetrate perpendicularly, making a radial network with numerous anastomoses. Immediately beneath the connective-tissue envelope this radial capillary network becomes a narrow-meshed plexus of rather wide capillaries which surround the cortex and communicate with numerous venous branches passing into interlobular veins. Together with venous trunks coursing along the surface of the cortical substance numerous veins and arteries are found in the medulla. In consequence there exists a double venous system, a superficial one between the adjoining cortices and a deeper one in the medulla; there is also a double capillary plexus, one superficial, the other radial.

The lymphatics of the thymus are still but little understood, our knowledge remaining practically where it was after His completed his studies upon the thymus of the calf, supplemented by the contributions of Watney and Renaut. According to His the larger blood vessels, which run along the central cord (calf's thymus) are accompanied by two or more lymph vessels, which receive one or more rootlets from each acinus. When these lymph vessels are traced, it is seen that in their further branching in the interlobular septa they soon lose their valves and muscular coat and become delicate-walled lymph spaces. These spaces plentifully surround the follicles. The lymph spaces provide an easy avenue for the thymic cells which are numerous in the thymic lymph

The nerves accompanying the thymic arteries are easily discovered. According to the investigations of Boveri, who employed the Golgi method, the nerves form a fine plexus upon the vessels and in the interlobular connective tissue, from which some fibrils penetrate into the medulla, terminating there with slightly swollen extremities (A. Kölliker).

Retrogression of the Thymus.—It has already been mentioned that the thymus is a temporary organ in man; that is to say, it does not remain in its condition of morphological (and presumably, therefore, physiological) perfection during life. That the thymus disappears more or less completely in adult life has long been known, but data relative to the exact time at which it passes away, and as to the stages leading to its backward metamorphosis, were not available until recent years. Indeed, even at the present time authorities are far from being in accord on all these points.

The views of Friedleben, whose work now over half a century old must be regarded as the classic on the thymus, are most generally accepted. He held that the organ reached its complete development at birth, remained in this condition (with some increase in size) until the second year of life, then gradually altered and atrophied, the retrograde process being well advanced by puberty. Variations in the course of these changes are by no means rare, and some of these are still misunderstood.

Accepting 20 gm. as the ordinary weight of the thymus, this remains fairly constant, under normal conditions, throughout life. But even with the unaided eye it may be seen that there is a marked difference between the thymus of a young child and that of an adult. In the first case the organ has a solid, flesh-like appearance, a uniform pinkish color, with well-defined and closely approximated follicles. No great excess of connective tissue is present, and but little fat occurs in the gland proper. In the case of the adult, however, all this is changed, and the organ appears as a fatty mass approximating the size and shape of the original organ. In this so-called "thymic fat body" of Waldeyer, reddish or dark yellowish foci, more or less discrete are to be seen up to the thirtieth year, and the microscope shows these foci to be remnants of the once voluminous gland. A marked change in the specific gravity of the thymus occurs with advancing years, as Dwornitschenko has shown, it being higher for the first thirty years and then becoming less. This is shown by its sinking in water during the first period and afterward floating, the fatty alteration being largely responsible for this variation. Such is the usual conduct under normal conditions, but the changes in the gland are profoundly affected by the general state of nutrition, and it also sometimes happens that the involution of the organ is retarded so that one finds in the adult an apparently perfect thymus, a solid mass of thymic tissue unchanged by fatty overgrowth, constituting the so-called "persistent" thymus. Persistent thymus is almost invariably an accompaniment of the dyscrasia known as status lymphaticus. (See *Status Lymphaticus*.)

So far as macroscopic evidences go we may summarize by stating that at the second year of extra-uterine life the thymus reaches its anatomical perfection, being a solid mass of adenoid tissue about 20 gm. in weight and sinking in water. From this period to puberty the organ gradually becomes smaller and distinctly tougher, owing to the increase of connective tissue in its substance; and at the same time its pinkish color fades. Between puberty and the twentieth year little change in bulk is noted, but it may be seen that adipose tissue is gradually appearing in the thymus, isolating the thymic substance into separate masses. This fatty alteration becomes more pronounced during the next two decades, the foci of thymic substance becoming smaller and more widely separated until finally a mass of yellowish fat, preserving the shape of the thymus, is all that the eye can detect—a mass that equals in bulk that attained at puberty, but that floats in water after the thirtieth year.

Histologically the evidences of a profound structural change during the retrogression of the thymus are well marked, and differ strikingly from what has been portrayed as the microscopic anatomy of the thymus at the period of its perfect development. These changes, which begin at the second year, have been particularly studied and described by Friedleben, Watney, Waldeyer, Schaffer, Sultan, Dwornitschenko, Lochte, and others. By these studies it has been determined that several distinct metamorphoses manifest themselves, the most pronounced being the connective-tissue, endothelioid, and fatty; that is to say, the process is one that affects both the framework and the parenchyma of the organ.

One of the earliest changes is the increase of interlobular tissue by which the acini become more widely separated, and, even before pronounced alterations occur in the acini, fat begins to make its appearance in the framework. There being no increase in volume of the organ, it follows that the proliferation of connective tissue produces a shrinkage or atrophy of the proper thymic elements, and in this the fat also plays a part, as Waldeyer has claimed. But while it must be regarded as a factor, pressure-atrophy is not the only condition incidental to the retrogression of the thymus. There is an atrophic change seemingly inherent in the cells of the thymic parenchyma. Sultan has directed attention to the other important retrogressive process—the endothelioid, which seems to be present at some stage during the transformation of the adult thymus in all individuals. From the endothelial cells lining the small blood-vessels and capillaries, and from those of the adventitia, endothelioid cells proliferate and appear both at the border and at the centre of the thymic acini. Sultan believes that some of these cells undergo a metamorphosis into fat cells. Later, spindle cells largely replace the endothelioid elements. A distinctly glandular or epithelioma-like appearance may be given to the thymus at the height of its endothelioid transformation.

Physiology.—The function of this organ, whose life history is so peculiar, is still much in the dark. Apparently its functional activity continues only during the stage of lymphadenoid development, though even at this time the presence of the thymus does not seem essential to life and well-being, since, according to the testimony of Friedleben and other experimenters who have followed him, the organ may be extirpated in young animals without causing any serious disturbance. Apparently contradictory to this conclusion are the results obtained by Thiroloix and Bernard in thymectomized rabbits, which died in three or four weeks with hypopyrexia and convulsions.

A number of authors have looked upon the thymus as a blood-forming organ, and Schaffer is the most recent advocate of this view. He believes, from his studies upon cats and rabbits, that the hæmatopoietic function is, like that of the spleen, liver, and bone marrow, a temporary one corresponding to certain growing periods; and, furthermore, he believes that the spleen and thymus maintain a reciprocal relationship, in that a rich supply of nucleated red blood cells in one is attended with a sparseness in the other. Carbone believes that the hæmatopoietic function of the thymus is limited to intrauterine life.

Since Friedleben's time the possibility of the thymus influencing the growth and nutrition has been considered. This point has been raised anew by Seydel, who, finding the thymus much atrophied or absent in infants dying from impoverished nutrition, concludes that the organ supplies blood or nutrient fluid. Tarulli, from his extirpation experiments, believes that increased appetite with augmented ingestion of food follows the operation, in spite of which the growth is retarded. There is also a diminution of hæmoglobin and of red blood cells with leucocytosis and eosinophilia. Von Braunschweig concurs with Tarulli in so far as denying a leucocyte-forming function to the thymus.

Experiments with extracts of the thymus have been made, particularly by Svehla, who used a ten-per cent. aqueous extract of the organ from man, dogs, swine, and cattle, and experimented on dogs by injection into the portal vein. He noted a fall of blood pressure, presumably caused by paralysis of the vaso-motors, acceleration of the pulse due to direct action on the heart, and death in narcotized subjects. In non-narcotized animals small doses caused restlessness and dyspnœa, while larger doses caused death with pronounced dyspnœa. Svehla compares the symptoms of experimental thymus intoxication with those of thymic sudden death (see *Status Lymphaticus*), and concludes that the fatal ending in the latter affection is caused by hyperthymization of the blood. Before accepting fully the conclusions reached by Svehla we should recall the fact that Cunningham has found that the toxicity of thymus and thyroid extracts is largely determined by the post-mortem changes in the glands after their removal and before subjected to the extractive process.

Pathology.—Besides various anomalies in the size, shape, and anatomical location of the thymus or portions of it, the organ may be completely absent. A typical example of this congenital abnormality has been reported by Clark in a baby of eight months; and while this reporter concluded from his observation that no serious nutritive disturbance followed the anomaly, he endeavored to show a relationship between the absent thymus and a form of hæmophilia from which the infant was suffering.

Circulatory disturbances as part of general vascular disease occur in the thymus. Venous hyperæmia is particularly prone to occur in the well-developed thymus with its large venous trunks, and has been repeatedly observed in asphyxia of the new-born. Punctate hemorrhages are found in some cases of sudden death in victims of status lymphaticus, and in the persistent thymus of lymphatic epileptics dying of asphyxia. They have also been noted in some cases of ordinary suffocation and in fatal phosphorus poisoning.

Atrophy of the thymus is a coincidence of general wasting of the body like that accompanying exhausting acute diseases or various chronic diseases attended by cachexia and marasmus. A well-developed thymus in an infant or a persistent one in an adult may shrink until little more than a fibrous-tissue mass remains to mark the place it once filled. This fact is important in connection with the anatomical diagnosis of status lymphaticus, a condition in which persistent thymus is associated with general lymphadenoid hyperplasia; for, under the conditions just mentioned, the organ atrophies and practically disappears, and, as a rule, the other lymphadenoid accumulations suffer the same fate.

Hypertrophy with hyperplasia of the thymus, which has had an overwhelming amount of attention in the literature concerning diseases of this organ, is almost invariably associated with the general condition known as status lymphaticus (see *Status Lymphaticus*), and should not be regarded as an independent affection. Even in the several cases in which the thymus has been reported as enlarged in Basedow's disease, myxœdema, Addison's disease, and acromegaly, other evidences of status lymphaticus have usually been disclosed.

Acute non-suppurative inflammations of the thymus are not common, and while the organ may participate in an inflammatory affection involving contiguous anatomical structures, it usually escapes. Biedert has reported a case of primary acute inflammation of the thymus unknown in origin. In general hæmatogenous infections the specific micro-organism may find its way to the thymus; and in certain pyæmic affections metastatic abscesses may occur in the thymus. There are also several cases on record in which single or multiple abscesses of the organ were found, with no evidence of a primary suppurative process elsewhere. In the cases of this character reported by Schlossman, Demme, and Helm, the enlarged thymus with its abscesses was apparently responsible for the sudden death.

Primary tuberculosis of the thymus is unknown, unless the questionable case of Carpenter's is so considered; but a number of instances of secondary infection, either in the form of miliary tubercles or in that of caseous tuberculous foci, have been noted

The thymus is the seat of various kinds of tumors, and is the starting-point of a considerable number of the neoplasms located in the anterior mediastinum. Various teratomas have been found in connection with it, the most common one being a dermoid cyst with hair, epithelium, and fatty contents similar to the dermoids of the ovary. A more frequent variety of thymic tumor is one taking a lymphoid structure and designated lymphoma or lymphosarcoma, depending on its extent and the production of metastases. However, since the lymphatic glands in the anterior mediastinum and about the bronchi may also become the seat of these tumors, it often becomes difficult to decide whether the thymus has been primarily or secondarily affected. The question may at times be determined histologically by the discovery of Hassall's corpuscles in the primary tumor. Besides the small celled lymphosarcoma, other varieties of sarcoma may occur, and carcinoma, presumably originating from the remaining foci of epithelial tissue, is occasionally encountered.

Extensive lymphoid infiltration and enlargement of the thymus may attend leukaemia and pseudoleukaemia.

Peculiar cysts of the thymus, probably at one time misunderstood and consequently designated Dubois's abscesses, have been carefully studied by Chiari, who regards them as originating from a growth of thymic tissue into the corpuscles of Hassall. Besides these spurious abscesses there are cavities with softened contents, properly called Dubois's abscesses, due to the softening of syphilitic nodules (small gummas). Syphilitic infection of the thymus may also manifest itself by a hyperplasia of the organ, or by a diffuse connective-tissue overgrowth with consequent induration. *A. P. Ohlmacher.*

LITERATURE.

As has already been mentioned, much of the literature upon the thymus, especially as to its hypertrophy and hyperplasia, should properly be classed with that bearing upon status lymphaticus. A particularly valuable paper giving the historical references is Ducrot's thesis ("De la Mort subite chez les jeunes enfants par hypertrophie du thymus au point de vue médico-légal," Paris, 1901). A more extensive work dealing with the thymus as a whole is Friedleben's monograph ("Die Physiologie der Thymusdrüse in Gesundheit und Krankheit," 1858). A thorough summary of the more recent literature is to be found in Klein's review ("Neuere Arbeiten über die Glandula thymus," *Cent. f. allgemeine Pathologie*, Bd. ix., Nos. 16, 17, 1898). From these three sources the student can obtain a reference to most of the literature dealing with the thymus except as pertains to certain special aspects of the embryology, anatomy, and histology, for which the standard text-books may be consulted.

THYROID.—ANATOMY.—There are few organs in the body that show normally so many and so great variations in structure, both gross and minute, as the thyroid. This is to be explained by the fact that it has its origin in three independent embryonal structures, so that in their fusion there are many opportunities for variations. Again, the absence of any excretory duct probably permits of wider variations than might otherwise occur, for no matter how arranged or where located the gland can accomplish its entire function, provided only that it has proper circulation. Ordinarily it presents two lateral lobes connected by an isthmus, which latter lies across the trachea from the second to the fourth tracheal rings, inclusive. This isthmus is absent in from ten to fifteen per cent. of individuals When present, it may merely consist of a mass of fibrous tissue containing a minimum of gland tissue, or it may form the largest of the three lobes, with all possible intervening variations. Quite rarely, *i.e.*, in about one per cent., the isthmus exists as an independent lobe. When the isthmus is absent the lateral lobes are often so closely applied that the absence of the isthmus may be completely overlooked. At the level of the isthmus, the recurrent laryngeal nerve lies in the angle between the œsophagus and the trachea, being covered externally by the lateral lobe on each side. In front, the gland is covered by the sterno-hyoid, the sterno thyroid, and the omo hyoid muscles. Laterally, the lobes extend outward in front of the common carotid arteries. The lower end of each lateral lobe is usually at the fifth or sixth ring of the trachea, and the upper end is at the middle of the thyroid cartilage. The lower edge is embedded in a mass of fatty connective tissue, which is of some surgical importance, since it passes without any demarcation into the anterior mediastinum. Behind, it is attached by tough fibrous tissue to the larynx and trachea, so that it moves with them in swallowing. When the head is thrown back, the distance of 2 mm. that lies between the lower border and the sternal notch is doubled (Sappey).

Frequently a conical process, called the "pyramid of Lalouette," extends upward to be attached to the hyoid bone, thyroid cartilage, or thyro-hyoid membrane. This may arise from the isthmus or from either or both lateral lobes, its shape and size also presenting wide variations. Its frequency varies greatly according to different observers. Marshall found it in 26 out of 60 thyroids, or 43 per cent.; Streckeisen in 104 out of 153; Zoja in 109 out of 147, or 74 per cent.; while the writer found it with 36 of 60 thyroids, or 60 per cent. In 10 of these last it arose from the right lobe, in 12 from the left, in 8 from the isthmus, in 5 from both lobes, and in 1 from the left lobe and from the isthmus. In 21 it was attached to the thyroid cartilage or thyro-hyoid membrane, and to the hyoid bone in 15. In one instance the pyramid was split up into a chain of isolated masses of gland tissue, which would have to be classified as accessory thyroids. In structure the pyramid generally consists of regular gland tissue near its base, but the colloid material disappears as it ascends, and the vesicles become mere groups of epithelial cells, which are gradually replaced by fibrous and muscular tissue, until near the upper part of the pyramid they disappear entirely. If the muscle fibres are numerous the upper part is considered a separate muscle, and called the *levator glandulæ thyroideæ*. The pyramids are considered by Bland Sutton to represent part of the original thyroglossal duct.

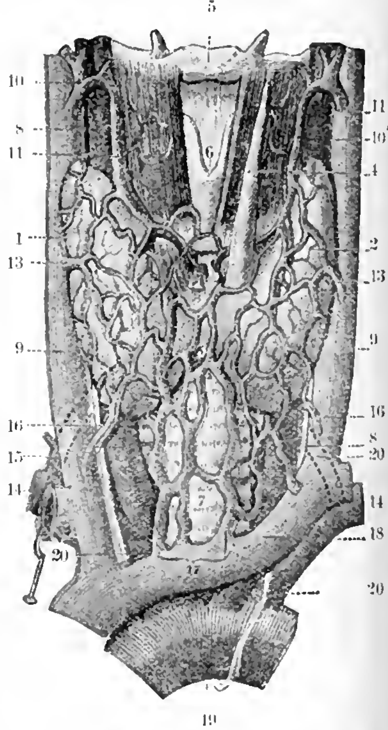

FIG. 4711. The Thyroid Gland and its Relations. (Testut.) 1, Right lobe; 2, left lobe; 3, isthmus; 4, pyramid of Lalouette; 5, hyoid bone; 6, thyroid cartilage; 7, trachea; 8, carotid artery; 9, internal jugular vein; 10', superior thyroid vein; 10, thyro-lingual-fascial vein; 11, superior thyroid artery; 12, inferior laryngeal vessels; 13, median thyroid vein; 14, subclavian artery; 15, inferior thyroid artery; 16, lateral inferior thyroid veins; 17, median inferior thyroid veins; 18, left brachiocephalic vein; 19, arch of the aorta; 20, pneumogastric nerve.

In proportion to its weight the thyroid has perhaps the largest blood supply of any organ of the body, the blood reaching it through the superior and inferior thyroid arteries on each side, and occasionally from the thyroidea ima. Following the trabeculæ these vessels break up into a rich meshwork of capillaries about the vesicles. In some places these capillaries even penetrate the basement membrane and come into direct contact with the secreting cells. So great is the vascularity, that when an active dilatation of its vessels occurs the gland increases noticeably in size, and in this condition a distinct pulsation can be felt throughout the gland. The veins unite to form the superior, middle, and inferior thyroid veins, the two former of which empty into the internal jugular vein, the last into the innominate. They are devoid of valves, and a rich plexus surrounds the gland, often causing much bleeding in operations. Some authors have described collections of a colloid like substance in the veins of the gland, and suggested that this was the method by which the gland disposed of its secretion, *i.e.*, directly into the circulation. However, these appearances are probably due to accidental extravasations occurring in the handling of the gland. It seems most probable that the excretion of the colloid substance occurs through the lymph channels, which are very numerous in the thyroid and lie in direct contact with the basement membrane of the vesicles, sometimes even with the gland cells themselves. In their lumen colloid is usually to be found, distinguished from other substances by its staining with Van Gieson's stain. After free anastomosis the lymph vessels leave the gland and pass through the superior and inferior deep cervical glands. (See description of lymphatics under "Tumors of the Thyroid.")

The nerves of the thyroid come from the middle and inferior cervical sympathetic ganglia, and pass into it with the blood-vessels. The recurrent and external laryngeal, the hypoglossal, and the vagus all send filaments to the gland, but these all seem to be vaso-motor or secretory, that is to say, they are all of sympathetic origin (Kölliker). The branches run to the bases of the epithelial cells, but the actual endings are not exactly determined.

The weight of the thyroid seems to vary greatly in different countries, since most German authors (Virchow, Rauber) place it at from 30 to 60 gm.; Schaefer in England gives it as 30–40 gm.; Poirier and Charpy in France give the average as 22–24 gm. In sixty thyroids removed in this country, I found the average weight but 22 gm. It would seem that in goitrous countries the normal gland is larger than in non-goitrous countries. The thyroid shows the effects of senility sooner and more than any other organ that is not essentially reproductive. In my series in persons over forty-five years of age the average weight was but 16 gm., while in people between twenty and forty-five years it averaged 25 gm. Differing from the other organs, it is larger, as a rule, in women than in men—a fact which, together with its early atrophy, indicates its close relation to the reproductive organs. It is relatively larger in infants than in adults; in the former the proportion to the body weight being 1 to 700 or 1,000, in the latter 1 to 1,500 or 2,200. According to Huschke there is even a decrease in size after birth, followed by a rapid growth at puberty. In the adult the transverse measurement is usually 50–60 mm., antero-posterior thickness of the lateral lobes 18–20 mm., of the isthmus 6–8 mm.; length of the lateral lobes 50 mm.; height of the isthmus, 5–15 mm. The right lobe is slightly larger when a considerable number of cases is averaged, although often in individual glands the opposite is true.

DEVELOPMENT.—Three separate "anlagen" unite to form the human thyroid. 1. A median diverticulum of the pharyngeal hypoblast pushes its way downward, and forms a tube that is connected with the base of the tongue. Subsequently it becomes solid, its upper end forming the foramen cæcum, from its lower end developing the isthmus, part of the lateral lobes, the pyramids (when they are present), and occasionally accessory thyroids. It sometimes happens that this structure remains in the adult as the "*ductus lingualis.*" 2. From the fourth visceral cleft on each side spring pouches which pass in front of the larynx and unite with the lower end of the median diverticulum, ultimately forming the outer part of the lateral lobes. These three masses fuse to form a horseshoe-shaped structure encircling the embryonic larynx, and are separated from their origin in the hypoblast. At first the gland consists merely of rod like columns of epithelial cells, resulting from the division and branching of its original rudiments. The ingrowing connective tissue divides these cords of cells into short

FIG. 4712.—Thyroid of Fœtus at Term. The lobular outlines are more prominent than in the adult; there is no colloid in the acini.

segments, which form the vesicles later, when colloid is secreted. Colloid formation begins in intra-uterine life, but the vesicles are not generally filled until some time after birth, section of the gland of a new-born child showing but few of the acini containing colloid. Because of the method of formation, in the fœtus a lobular structure is distinct, but in the adult this is generally absent or indistinct.

HISTOLOGY.—Fully as great variations are seen microscopically in the thyroids of persons who die of diseases that have no known effect on the thyroid, as have been noted in the gross anatomy. Study of the thyroids from consecutive autopsies shows such a variety of conditions as to suggest that perhaps this organ suffers much more in disease than we have reason to suspect from any clinical evidences. What may be considered the normal structure is described most briefly by saying that it differs from other tubular glands chiefly in having the tubules closed and filled with colloid to varying degrees of distention. The arrangement of capsule, septa, basement membrane, vessels, and nerves is that common to glandular organs in general. By reconstruction methods Streiff has shown that the vesicles are not always spherical sacs, but often are tubular, and frequently are sacculated. The size of the vesicles varies greatly, some being quite without lumen, while others are more than half a millimetre in diameter. As the epithelial cells are modified by the pressure of the colloid in the lumen of the acinus, they vary much in size and shape from those that are distinctly columnar in empty acini to those flattened, in distended sacs, to the nature of an endothelial cell. For the most part they are cuboidal, with a small spherical nucleus that stains more intensely than that of most epithelial cells. They are described as of two kinds—the chief cells and the colloid cells. The chief cells, which form by far the greater part, are clear or with very fine granules and have no distinct membrane, but seem to blend with one another, their outer ends resting on the basement membrane, the inner lying in the colloid substance. The colloid cells are characterized by a more granular and opaque appearance, obscuring the nucleus, and they are lower than the chief cells, from which they seem to be derived. The granules stain like colloid, and they seem to become converted into this substance, to be replaced by new cells from the chief cells. All stages between these forms may be found. Acidophile granules are also described, which are considered analogous to the zymogen granules of other glands. The colloid content of the alveoli stains a clear pink-white eosin, and is usually structureless. Often, however, nuclei or entire cells are present, but the frequently observed total exfoliation of the epithelial cells into the colloid is probably to be interpreted as a post mortem occurrence, quite the same as the desquamation of the endothelium of blood-vessels. Red corpuscles are frequently found, apparently normally, and it is stated that they will retain their form and staining properties for a very long time in the colloid. However, pigment from this source is frequently present. The vacuoles that often fringe the colloid are probably for the most part, if not entirely, the result of shrinkage in the hardening process. Ernest considers the orange, or yellowish brown color assumed by the colloid when stained by Van Gieson's method to be characteristic, but this is by no means constant; sometimes it gives a good red color. Fat is constantly found in the epithelial cells of the thyroid as well as the parathyroids and hypophysis, increasing in amount with age (Erdheim).

The stroma of the gland is scanty in the adult, but more abundant both in infancy and in old age. Larger septa of very dense fibrous tissue separate the original lobules of the gland, while bands that are often extremely thin separate individual acini. In it are the wide, colloid filled lymphatics, the abundant vessels, and the nerve fibres, which are mostly non-medullated. There are no intrathyroid ganglia, but simple ganglion cells of very irregular form, which, as a matter of fact, are not fully distinguished from branched connective-tissue corpuscles (Poirier and Charpy). Between the follicles are often found groups of cells that seem to indicate undeveloped follicles, even to the extent of sometimes containing colloid droplets. What are considered to be embryonal rests are found, especially under the capsule.

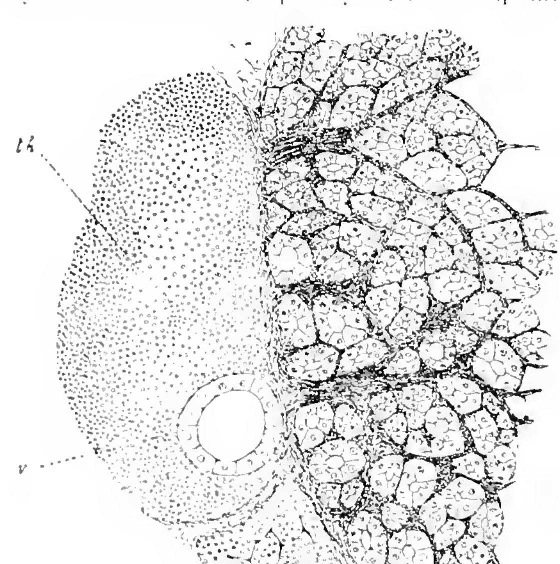

FIG. 4713. Parathyroid, Thymic Vesicle, and Thymic Lobule of New-Born Guinea-pig. (Poirier and Charpy.) *th*, External thymic lobule; *v*, thymic vesicle; *g.l.* external parathyroid.

The cells lie with little order in the stroma, and have large, chromatin rich nuclei and little cytoplasm. Their exact nature is not settled. Bozzi found no alterations in embryonal rests present in small stumps of gland tissue remaining after removing the greater part of the gland, nor did their presence prevent the death of the animal, suggesting that perhaps they are not really embryonal rests.

Parathyroids.—These organs are composed of columns of epithelial cells, with large, deeply staining nuclei, and a rather small amount of cytoplasm. They resemble the carotid glands in structure, but the thyroid not at all, and it is considered by Prenant that they are derived from the fourth inner branchial cleft, from which the thymus and the lateral rudiments of the thyroid are also derived. Gley believed that they represented embryonic rudiments of the thyroid, but, as will be shown later under Physiology, this interpretation is not correct. For further description of these organs see under *Goitre*, Vol. IV., p. 378, and under *Parathyroid*, Vol. VI., p. 506.

Thymic Lobules.—As a rule these little-known bodies are four in number, but sometimes there are but two, and in some animals they are lacking (Nicolas). There are two external lobules, usually on the posterior surface of the lateral lobe; and two internal lobules, in the centre of the lateral lobes, surrounded on all sides by glandular tissue, or sometimes they are near the tracheal face. They possess the structure of the thymus, even to the concentric epithelial corpuscles, but they are often mistaken for lymph nodules. They are ascribed to the common origin of the lateral lobes of the thymus and thyroid in the fourth branchial clefts. They seem to occur infrequently in man (Müller). Besides these normal structures not rarely rests of thymus tissue are found in the thyroid gland, or about it.

Ciliated Vesicles.—Vesicles lined with ciliated epithelium are occasionally found, not only in the thyroid, but in the parathyroid, or thymic lobule (see Fig. 4713), or in the thymus; they may give rise to cysts. Their content is a clear fluid, quite different from the colloid. They are probably derived from the original pharyngeal or branchial diverticulum, and persist as does the thyroglossal duct.

CHEMISTRY.

Until 1896 the thyroid was studied frequently to learn something of its chemistry, because as a gland with internal secretion it seemed possible that this unknown secretion might be found. It was learned that it was rich in the various extractives, indicating metabolic activity, and that it contained a nucleo-proteid and a globulin of some interest. Fraenkel thought he had isolated an active principle in a crystalline, alkaloid-like body, apparently belonging to the guanidin series. Baumann in 1896 succeeded in isolating the real active principle in the iodine compound, *thyroiodin* or *iodothyrein*. This, according to Baumann, is a brownish, amorphous compound, remarkable for its resistance to chemical and physical agencies; it can be boiled for days with ten per cent. sulphuric acid or undergo prolonged digestion with gastric juice without alteration. This explains its successful use per os therapeutically. It is almost insoluble in water; in alcohol it dissolves with difficulty. It manifests no proteid reactions, and in the purest specimen that Baumann was able to obtain, he found 9.3 per cent. of iodine, which is probably below the true proportion. Working with Baumann, Roos subjected it to physiologic and therapeutic tests that showed it to be the active principle of the gland. There seem to be no essential differences in the substance as obtained from either human glands or from the lower animals. However, the variations in the amount of iodine found in the glands of individuals in health is great, but it may be stated that in goitrous districts the amount of iodine is much less than in the places where goitre is rare. This is shown by the accompanying table.

The manner in which the iodine is combined in the thyroiodin is still unknown, although according to the work of Oswald it is preponderatingly, if not entirely, united to aromatic groups. However, it is known that the iodine is combined in a non-proteid body, the thyroiodin, which in turn is combined with a proteid, forming the

Place.	Dry weight of glands.	Iodine per gram in milligrams.	Total milligrams iodine.	Frequency of goitre.
Freiburg	8.20	0.33	2.50	Endemic.
Hamburg	4.60	.83	3.83	Not endemic.
Berlin	7.40	.90	6.60	Not endemic.
Chicago	5.37	2.10	10.79	Not common.
Boston and New York	4.47	2.64	11.80	Not common.
Baltimore	5.41	2.36	12.76	Not common.
Montreal	4.49	2.40	10.77	Not common.

thyroglobulin. This thyroglobulin contains 1.6 per cent. of iodine, and is found entirely in the colloid of the gland, but it is not the sole ingredient of the colloid, which contains a neucleoproteid also. Oswald believes that the iodine is united with the globulin either just as it is excreted from the cells or after it is in the acini; a thyroglobulin devoid of iodine may be found under some conditions. The thyroid of new-born infants, as well as of calves and other young animals, is either devoid of demonstrable quantities of iodine or contains but traces, and in them a colloid containing globulin free from iodine is found. Many experiments have shown that the functional activity of the thyroid, whatever it may be, is due entirely to this iodine compound, acting not as iodine or as an iodide, but specifically as thyroiodin. Whatever effects can be obtained by administration of the entire thyroid can be as well obtained with the pure thyroiodin. There is no evidence of any function on the part of the nucleoproteid. The thyroid, then, differs from ordinary glands simply in having the lymph vessels for its excretory ducts. What becomes of the thyroiodin after it is eliminated from the gland is unknown, but it is thought that the iodine is returned to the gland after it has performed its functions, to be rebuilt into thyroiodin. Iodine cannot be found in the other organs in appreciable quantities, although infinitesimal quantities are said by some observers to be quite widespread. If large quantities are administered to animals iodides appear in the urine (Blum), but according to Oswald physiological doses do not lead to its appearance in quantities that can be detected. Nor is it known in what manner it is taken up by the gland, whether from unknown tissue iodides, or organic iodine compounds, or from minute traces that exist as iodides in the water and air. It is known that when iodides are administered therapeutically the colloid becomes richer than normal in iodine, but it is questionable if the iodides are converted into thyroiodin before exerting their effects. Administration of bromides does not influence the iodine content of the thyroid, and there is no storage of bromide in the gland. Administration of pilocarpine does not increase the thyroiodin.

The colloid seems to vary greatly in its composition, but as a rule the more colloid there is in a gland the less the proportion of iodine, so that the total iodine content is kept nearly constant under normal conditions. This is far from true in the goitres, for some are nearly devoid of iodine, while others contain much greater quantities than normal. In goitres, while in a way the amount of iodine increases with the amount of colloid, yet this is only partly true, for the greater the amount of colloid the less its proportional amount of iodine. Oswald has found that in colloid goitres this is due to the accumulation of a globulin in the colloid that differs from thyroglobulin in not possessing any iodine. In the parenchymatous form of goitre, in which microscopically the enlargement is due to the development of enormous amounts of epithelium with very little colloid, the amount of colloid in each part of gland tissue is much lower than normal, although the total amount will usually approximate that found in the normal gland. The scanty presence of iodine is not due to an inability of the gland to combine it, for in the goitrous thyroids of people who had received iodides before death the amount of iodine has been found to be large. In exophthalmic goitre the proportional amount of iodine has generally been found to be small, although here, too, the gland has been found by Oswald to be capable of utilizing iodine administered therapeutically. The colloid from goitres, so far as it contains iodine, possesses the same physiological properties as the thyroglobulin from normal glands, but in less quantity. If free from iodine it is entirely inactive (Oswald).

According to Gautier the thyroid contains about 0.75 mgm. of arsenic in each 100 gm. of substance, and is the richest in arsenic of any of the tissues of the body. He considers that it is bound to the nucleoproteid of the colloid, perhaps substituting for phosphorus, and that it is of physiological importance, especially in relation to sexual phenomena. The amount of arsenic is too small to cause confusion in medico-legal matters.

Physiology.

Most of our knowledge of the action of the thyroid gland is based upon the changes observed in man and animals when they are under one of two conditions, which are:

1. When the animal is receiving less than the usual amount of secretion from the thyroid, as in extirpation experiments.

2. When the amount of secretion in the body is above normal, as when thyroid extract is being administered.

These observations include not only the results obtained by experiments, but also those obtained from clinical observations, since here the symptoms are due sometimes to hypo activity, *e.g.*, myxœdema and cretinism; or to hyperactivity, as sometimes in therapeutic use of thyroid, or after operations, and possibly in exophthalmic goitre.

In the first case when the subject is receiving less than the full influence of the thyroid gland, we observe symptoms that may be divided into nutritional and nervous.

(*a*) The nutritional changes seem to be of such a nature that the metabolic changes throughout the body do not proceed to their full extent, or are reduced in rate, and the power of cellular reproduction is altered. As a result of the first the connective tissues stop in their metabolic processes just short of completion, leaving them, as Semon suggested, in an embryonic condition, that is, in the form of myxomatous tissue, which is their embryonic representative. From this results the condition of the skin seen in myxœdema. This change seems not to be confined to the subcutaneous tissues, but is a general change, for Halliburton has shown that in the blood of monkeys rendered myxomatous as a result of thyroidectomy, there is demonstrable a considerable quantity of mucin. Because of the failure of complete cell reproduction, or an alteration in the process, we observe a change in young animals, quite analogous to cretinism in children. Besides this, there is a decrease in the gas exchange of the blood, for in thyroidectomized animals the amount of carbon dioxide is increased and the oxygen diminished until the arterial blood may be below the normal venous standard. The urine indicates that all metabolic changes are lessened. Oligocythæmia is usually marked.

(*b*) The nervous system is apparently greatly affected, the most marked symptoms from this source being those due to the excitation of the muscular fibres, viz., twitching, tremors, and spasms. These seem to proceed from the lower centres, for Horsley has observed them in monkeys subjected to ablation of the motor cortex, and Munk found that they were not affected by division of the cord, while Schiff showed that they were not of peripheral origin by finding that section of the motor nerves stopped them. Degenerative changes have been found in the anterior horn ganglion cells of thyroidectomized dogs. Later, these symptoms are followed, if the animal survives, by a lessening of the power of voluntary action, as well as by loss of sensation. The thermotaxic apparatus is also affected, so that the body temperature falls three or four degrees below normal. Lorrain Smith has observed that the reaction of thyroidectomized animals to changes of temperature is abnormally rapid, so that if such an animal is exposed to cold the production of carbonic acid is increased immediately, instead of being delayed for some time as in normal animals. Moreover many of the symptoms of athyreosis are alleviated by artificial heat.

The clinical picture resulting from the above-described changes is referred to as *cachexia strumipriva*, or *thyroid cachexia*.

When the thyroid preparations are administered to animals experimentally, or to man therapeutically, opposite effects are produced.

(*a*) *Nutritional.*—Metabolism throughout the body undergoes an increase, shown best by the urine. This is considerably increased in quantity; it contains a greater amount of urea as well as chlorides and phosphates. At the same time the weight of the patient decreases, particularly if it is above normal on account of fat deposition. This decrease in weight is constant and considerable, and, according to Wendelstadt, but one-sixth can be attributed to destruction of proteid, as indicated by the urinary nitrogen, the rest being due to loss of water and of fat through increased oxidation. In young individuals of stunted growth the height is often increased.

(*b*) *Nervous.*—Of these, palpitation of the heart is often one of the most prominent. With it come headache, nausea, and vomiting, if the dose is very excessive, and the heart may weaken to a dangerous degree. The patient is excitable, irritable, and often sleepless. Diarrhœa often sets in, and in some patients taking thyroid extract continuously in myxœdema and cretinism the condition of the bowels is found a good guide to the amount of the extract to be administered. Sometimes glycosuria is produced, which in a few instances is said to have developed into a true diabetes mellitus. Schaefer has also shown that if thyroid extract is injected into the veins of healthy dogs there follows an immediate fall of blood pressure due to general vascular dilatation.

It is to be noted that the symptoms that are attributed to the thyroid may be due in part to the parathyroids, which according to some experiments seem to be really more essential to the individual than the thyroid itself. There is a tendency to attribute much of the nervous manifestation to the parathyroids, while the metabolic processes are credited to the thyroid. According to Hutchinson, removal of the thyroid alone probably causes myxœdema, while removal of the four parathyroids causes the acute tetanic symptoms. (See article on *Parathyroid*.)

From the facts noted above have been developed two theories to explain the action of the thyroid. One assumes that the thyroiodin that has been excreted by the gland neutralizes a toxic material, either while passing through the thyroid in the blood, or, more probably, while circulating in the blood stream of the body as a whole. This hypothetical toxic substance may come either from alimentary absorption, or from metabolism, as an abnormal or normal intermediary or end-product. The other theory advocates the idea that thyroiodin is essential in normal metabolism. It suggests that thyroiodin may be essential for certain of the normal cell processes, much as calcium salts are involved in the coagulation of the blood. Either of these theories may be applied to most of the known facts, but neither is entirely satisfactory. One of the strongest evidences in support of the antitoxic nature of thyroiodin is furnished by Blum, who found that ninety six per cent. of his thyroidectomized dogs died when fed upon meat, while but sixty per cent. died when they were fed upon milk. Dogs that were getting along well on a milk diet developed symptoms of athyreosis when fed upon meat. Hence it is considered by him that symptoms that follow thyroid extirpation are produced by substances formed by the meat in the gastro intestinal tract, which are produced in less quantity by milk, and which the thyroid normally neutralizes. It is, however, probable that milk contains thyroiodin, for young calves are said by Oswald to have iodine in their thyroids, and he believes that the deficiency is supplied by the mother's milk, for, as is well known, the maternal thyroid is hypertrophied during gestation and lactation. He is inclined to think that if there is a toxin it is one of the normal intermediary products of metabolism which does not undergo its usual transformations because of the general decrease in metabolic activity.

That there is a close relation between the thyroid and the reproductive functions, particularly in the female, is beyond question. This is shown by its enlargement during menstruation and pregnancy, its early atrophy after the menopause, its greater size in the female, its tendency to develop goitre during pregnancy, and the loss of sexual appetite in many of the thyroid diseases. It is stated that from eighty to ninety per cent. of all cases of goitre and eighty six per cent. of the cases of myxœdema are in women, and Graves' disease occurs chiefly in females. Halsted observed that bitches that had lost part of their thyroids, but not enough to give rise to symptoms, when impregnated showed evidences of athyreosis as the time of parturition approached, which disappeared soon after the litter was born. Further, in all of the pups of these litters the thyroid glands were many times the normal size of the glands of pups of the same weight. Just what part the thyroid plays in pregnancy is unknown.

It may be that it hypertrophies to supply the needs of the fœtus, which, as we have noted, does not form thyroiodin in its thyroid, and whose needs must be great if thyroiodin is necessary for cell growth. As to the hypertrophy of menstruation, Gautier claims to have demonstrated both iodine and arsenic in menstrual blood as well as in the thyroid, and he believes that the latter supplies the former. It has been thought by some that the thyroid may play a rôle in the production of puerperal eclampsia. One writer states that hypertrophy of the thyroid is absent in eclampsia, and ascribes this disease to thyroid inefficiency. In this connection the experiments of Blum are of interest. He found that in the dog thyroidectomy was followed by albuminuria almost constantly, sometimes with hæmaturia, and accompanied by marked renal lesions if the animal survived long enough to develop them. Alterations in the central nervous system, affecting chiefly the Nissl bodies, have been described by Blum and other observers.

Lange sums up the relation of the thyroid to pregnancy as follows: A physiological hyperplasia like that observed in the thyroid in pregnancy has never been found in the kidney at this period. Pregnant animals need a larger thyroid than those not pregnant. When a piece of thyroid just sufficient to continue life in a non-pregnant animal, is allowed to remain in a pregnant animal, an insidious kidney disease develops, one that may result in convulsions and coma, which are not relieved by thyroiodin, and which are distinct from the convulsions of tetany.

The marked atrophy of the thyroid in old age has been regarded as indicating some possible influence on senility. More probably it is related to the decline of sexual life. It is interesting to note that the thyroid arteries are prone to show very early sclerosis, often before other vessels are at all affected. The decrease in red corpuscles after thyroidectomy is probably the result of the decreased activity of the blood-making organs, or it is dependent upon an increased destruction by toxic substances. The decrease is not, as was once thought, an indication of hæmatopoietic properties of the thyroid. Another old theory, probably baseless, was that the thyroid was a reservoir into which the carotid blood might be shunted to produce cerebral anæmia and thus favor sleep.

Pathology.

Malformations.—Because of its manner of development the form of the thyroid is very inconstant, and this matter has been in part discussed under the subject of anatomy. The commonest alterations from the usual form are absence of the pyramids, or of the isthmus; the latter may also be of peculiar shapes, and it has been known to pass between the trachea and the œsophagus. Hypoplasia, and even total absence, may be observed in cretinism, and it is usually absent in acephalics. Hektoen has recently reported a case of dwarfism, related to the type of achondroplasia fœtalis, in which the very small gland was nearly devoid of epithelial elements, and contained no demonstrable iodine. Unilateral glands are uncommon. Many abnormalities of form are produced by the formation of colloid cysts, and by the cicatricial contraction of healed cysts.

The *thyrolingual* duct may fail to become obliterated, remaining as a canal which extends for a longer or shorter distance from the foramen cæcum; occasionally residual portions of this duct become dilated into cysts of varying size. These cysts may open and form a median cervical fistula, usually opening below the cricoid cartilage, and lined either with stratified or with columnar epithelium. Lingual dermoids and tumors at the base of the tongue have been traced to this origin.

Accessory thyroids are of a structure identical with that of the thyroid, although they sometimes reproduce rather the fœtal than the adult type. They are far from constant in occurrence, or location, or numbers. In general they are located in an isosceles triangle which has its base at the lower jaw and its apex at the aortic arch. The most frequent location is in the vicinity of the hyoid bone, and they have been found within the bone itself. Many of them are attributable to remnants of the diverticulum that ordinarily forms the pyramids, often replacing this structure. Of particular practical importance are those found within the larynx or trachea, for these may give rise to marked symptoms. Thiesen found in the literature 10 positive and 2 doubtful cases of this sort, 8 of which occurred in Germany. Of 91 benign intratracheal growths which Bruns in 1898 collected from the literature, 7 were of thyroid origin. The structure is usually the same as that of normal thyroid, and, like it, contains colloid. Accessory thyroid may be the result of inclusion of an accessory thyroid lobule in the larynx or trachea in intra-uterine life, or the membrane between the rings of the trachea may be penetrated by adherent thyroid tissue during later life. Usually the growth is located on the posterior or on the lateral wall, being attached by a pedicle to the thyroid. Seven of the 10 cases were in women, and were detected usually between the fifteenth and thirty-third years. In Thiesen's case dyspnœa was increased by pregnancy. In only 2 cases did goitre coexist. One case of thyroid tumor at the base of the tongue is of particular interest, in that its removal was followed by symptoms of myxœdema, which were relieved by thyroid therapy (Shurley). Here it would seem probable that atrophy of the gland proper had resulted in a compensatory hypertrophy of the remnants of the thyrolingual duct.

Circulatory disturbances of the thyroid are prominent because of its great vascularity, but they cause relatively little trouble unless the gland is already enlarged, when the added size may be of importance.

Passive congestion may occur in heart disease and from pressure on the cervical veins, but it is rarely evident, has no apparent effect on the function of the organ, and it seems not to cause structural changes of moment.

Active hyperæmia is frequent, usually physiological, and it is held responsible for the visible enlargement of the gland in menstruation, pregnancy, sexual excitement, and at puberty. However, it is not always easy to determine how much of the enlargement is due to the vascular dilatation, and how much to hypertrophy of the gland elements or to increased production of colloid, since all these may go together. At times it may be so great that a distinct bruit can be heard over the gland; this is particularly the case in Graves' disease. In various forms of goitre (*q.v.*) hyperæmia is present; in fact, a vascular form has often been mentioned in the literature, although it is very doubtful that there is such a thing as a real goitre produced solely by vascular enlargement. Probably the active hyperæmia of sexual origin is the same as that of other glands during physiological activity. Sudden hyperæmia may cause severe, even fatal attacks of dyspnœa when the glands are goitrous. So in pregnancy dyspnœa is always increased if it existed previously, or it may appear first at this time.

Infarction does not seem to occur, the circulation being too free. If emboli lodge there they seldom seem to cause effects, for even in pyæmia, miliary tuberculosis, and vascular dissemination of malignant growths the thyroid escapes more often from secondary lesions than do other organs, particularly if the great amount of blood that it receives is considered.

Hemorrhage is a prominent feature of the goitres, but it also seems to occur even in the normal gland. The red cells are preserved for a long time in the colloid, but eventually give rise to accumulations of pigment and cholesterin crystals, which latter may be very abundant. Any trauma of the thyroid is likely to give rise to hemorrhage, either into the vesicles or into the periglandular tissues. Large intraglandular hemorrhages may soften and lead to cyst formation, or become infected.

Progressive Changes.—Thyroid tissue has great vitality, and there is no other gland that can be transplanted so successfully. As the secretion is removed by the circulation any transplanted portion can functionate, and the treatment of myxœdema w s first successfully accomplished by grafting. An important fact, in view of the study of cytotoxins, is the following: transplantations can be made from one species into another with perfect results For example, sheep thyroid has been implanted into man and has cured myxœdema, showing that the secretion is practically the same in the different species. At first, the graft undergoes considerable necrosis and is partly absorbed, but some cells remain alive, and from these develop thyroid tissue in proportion to the needs of the body, for thyroid tissue has almost unequalled capacity to undergo compensatory hypertrophy. Grafts removed after four and one-half years have been found of the same structure as normal or hyperactive thyroid.

During hyperactivity, whether compensatory or not, the gland shows a decrease in the amount of colloid in the vesicles, as if it were being absorbed as fast as formed. The epithelial cells increase in size, either because of lack of pressure from colloid or because of formative or secretory stimuli, and the walls are thrown into folds so that the secreting surface is increased. Such changes as this were observed by Halsted in remnants of glands left after partial thyroidectomy, and they are seen in many cases of exophthalmic goitre, supporting the theory of the origin of this disease in thyroid hyperfunction. But a small remnant of the gland needs to be left in most cases to enable the demands of the body to be met, and not only normal gland tissue, but accessory thyroids and even tumor metastases, may functionate adequately.

Hypertrophy of a simple nature seems to be the process which causes many goitrous enlargements, and it is undoubtedly physiological in many instances, in response to some unknown demand of the body for increased activity. It is probably in such cases that operation is particularly likely to be disastrous. In acromegaly, associated with disease of the hypophysis, the thyroid is often enlarged, as it also is in many cases of giantism The hypertrophy of pregnancy is undoubtedly physiologic.

Retrogressive Changes.—*Atrophy* occurs prominently in old age, and is accompanied by a relative increase of the connective tissue, and a decrease in the amount of both colloid and epithelial elements This is without evident effect on the individual, and seems to be secondary to decreased needs of the organism. It has been suggested that it may have a relation of primary importance to senility In this connection it is to be noted that sclerosis of the thyroid arteries seems to occur particularly early in life. In youth atrophy sometimes gives rise to cretinism, while in adults it may lead to myxœdema However one may find very small thyroids in individuals who show no evidences of any thyroid deficiency. The gland has been found atrophied in scleroderma (Hektoen), and in various forms of dwarfism that were quite different from cretinism. Katzenstein found section of the nerves of the thyroid to be followed by marked atrophic changes.

Parenchymatous Degeneration.—Studies of the histology of the gland in various intoxications by different observers have been reported as showing many changes in the way of epithelial proliferation or desquamation, increase of stroma, etc., but the results have been so inconstant, and the structure of the thyroid is so variable, that little importance can be attached to them. It may be that in infectious diseases injury to the thyroid leads to detrimental effects to the individual, but if this is so there are no clinical or anatomical evidences to show it. Slight changes have been described in the thyroid following experimental operations in the bile ducts (Wiener, Müller, Hürthle).

Amyloid deposition occurs in either the normal gland or in goitres as a part of general amyloidosis, affecting here as elsewhere the arteries and stroma chiefly. In one hundred and eighteen autopsies in which amyloid disease was found at St. George's Hospital, amyloid was noted in the thyroid but once, but this is probably to be attributed to lack of search for it there. In goitre occasionally local deposits of amyloid may cause wax-like nodes, similar to local amyloid deposits that have been found in the larynx.

Hyaline degeneration is frequent in the stroma of goitres, in senility, and in tumors. It frequently is followed by calcification.

Fatty degeneration is not prominent in the thyroid, but may accompany the same changes in other organs. According to Erdheim, there is normally some fat in the epithelium of the thyroid.

Calcification of the stroma and arteries may occur in senility, and sometimes earlier in life. It is very common in goitres, especially in the walls of old cysts, which may be entirely enclosed in a shell of calcified material. Rarely ossification follows. The finding of areas of calcified materials in goitre is a frequent occurrence in autopsies.

Infections.—*Acute inflammation* of the thyroid is, on the whole, very infrequent. It is much more likely to occur in goitrous glands, which condition is sometimes called *strumitis*, to distinguish it from inflammation of non-goitrous glands, or *thyroiditis*. It would seem that the normal gland possesses in a marked degree the power of resisting infections, a characteristic that is perhaps due in part to its great vascularity, which is lost in the goitres with their frequent areas of degenerated tissue. When acute inflammation does occur it is nearly always suppurative, and the pus may burrow in disastrous ways in the tissues and organs of the neck. Infection may come through the blood stream, which is most frequent, or from extension from surrounding structures, or from direct external injuries, as in attempts at suicide by cutting the throat. Of 20 cases Lancereaux found that 4 occurred in the puerperal state, 3 in typhoid, 2 in nephritis, 2 in pyæmia, 2 in pneumonia, 1 in acute articular rheumatism, and 6 were independent of other diseases. Later observations have shown that of the febrile diseases thyroid infection is particularly frequent in typhoid, Schudmark having collected 13 authentic cases. Termination is most frequent by rupture and cicatrization, when the infection is not a complication of a mortal disease, although gangrene has resulted in several cases. In goitres the pus may accumulate in cystic spaces until large accumulations result. Of particular interest are the few reported cases in which myxœdema, cretinism, and Graves' disease have followed the healing of such destructive inflammations.

Chronic interstitial inflammation with formation of connective tissue may occur; little, however, is known about such a process. Probably certain cases of myxœdema, and perhaps of cretinism, are produced in this way. Often at autopsy thyroids are found that show so much fibrous tissue that the suspicion of an interstitial thyroiditis is warranted, but as no results seem to have been produced by the lesion, and as there is no apparent cause, the condition is of no evident practical interest.

Tuberculosis occurs most frequently in generalized miliary tuberculosis, but naturally is overlooked clinically, and often at autopsy. Chiari found lesions in the thyroid in seven per cent. of his cases of pulmonary tuberculosis, and in twelve per cent. of Fraenkel's fifty cases they were present. Miliary tubercles are much more frequent than the larger caseous nodules. They generally start in the interacinous connective tissue. There are three cases in the literature in which, so far as clinical manifestations showed, the thyroid lesions were primary. Tuberculosis of the cervical glands seems to be transmitted to the thyroid much less often than might be expected. According to Roger and Garnier sclerotic changes are constant in the thyroid in chronic phthisis.

Syphilis might be expected to spare the thyroid in view of the large amount of iodine that the gland contains, but it cannot be said that syphilis is proportionately less frequent than other infections of this organ. Gummata have been occasionally observed, although scar formation of the irregular, deforming type seen in other organs is perhaps as frequent. During the stage of intoxication the thyroid often participates in the general glandular enlargement. In congenital syphilis thyroid gummata are not rare, although a diffuse sclerosis is more frequent, and cases of cretinism have been attributed to the thyroid sclerosis of congenital syphilis. Myxœdematous symptoms have resulted from syphilis of the thyroid in a few instances; they were relieved by antisyphilitic treatment.

Actinomycosis may result from extension by way of the cervical fascia, and a number of such cases have been reported. Metastatic actinomycotic infection does occur, although very infrequently.

Cytotoxins.—In connection with the general study of the formation of toxins for different animals by immunizing them against various tissues from a different species attempts have been made with the thyroid. The only reports published at the time of this writing are by Gontscharukov and Mankovsky, each of whom, after injecting the immune serum into dogs obtained symptoms that were considered comparable to those resulting from thyroidectomy. Their work is, however, limited, and other more extensive work, as yet unpublished, furnishes results which are by no means corroborative.

In this connection may be mentioned the recent trials of the serum and of the milk of goats in the treatment of exophthalmic goitre. These trials have been made on the assumption that this disease is due to hyperactivity of the thyroid, and that the serum and milk of goats contains an excess of the substance that the thyroid should neutralize. Lanz, and also Moebius, have tried this treatment, and both consider it of positive benefit.

Tumors.—*Benign tumors* of the thyroid, if of epithelial nature, are difficult or impossible to differentiate from hypertrophy of compensatory or functional nature; they are all described in the article on *Goitre*. Benign mesoblastic tumors are rare, although fibromas, chondromas, and osteomas have been described. They present no special peculiarities because of their origin in the thyroid.

Seventy to eighty	3	2
Eighty to ninety	1	..

Malignant tumors have also been discussed in the article on *Goitre*, but since its publication the elaborate study

Thyroid.

of all available cases by Erhardt has appeared, and a rather full abstract of this in English may be of value. Trustworthy reports were found of about 150 carcinomas and 100 sarcomas. Of the carcinomas 65 occurred in

FIG. 4714.—Primary Carcinoma of the Thyroid.

men and 85 in women; of the sarcomas 40 were in men and 59 in women, these results agreeing with the general prevalence of thyroid diseases in women. The preceding table shows the age status of the malignant tumors.

It will be noted that the usual earlier occurrence of sarcoma is not the rule in thyroid tumors, for which fact there is no evident explanation. Trauma seemed to be the starting-point of the tumors in 3 cases, while in 3 others acute infectious disease preceded the growth, and in 2 it accompanied pregnancy. Out of 200 reports it is expressly stated that goitre preceded the tumor in 104; in but 21 was the absence of goitre specifically noted, while in the remainder this point was not mentioned. In view of the great frequency with which nodules are found in thyroid glands that are not enlarged, it is possible that in even some of the 21 cases in which there was no goitre, some small goitrous nodules existed. A location of the goitre behind the sternum seems favorable to malignant transformation, probably because of irritation. Naturally, thyroid cancer is more frequent in goitrous than in non-goitrous districts.

Anatomical Features.—Carcinoma is not to be distinguished from sarcoma by any clinical features, and anatomically also these two varieties of new growth resemble each other more closely when they are located in this organ than when they develop in almost any other organ in the body. Occasionally the growth is so diffuse from the start that its origin cannot be determined. For some time the capsule seems to offer a barrier to extension, but invasion of both blood and lymph vessels occurs early. Although sometimes of enormous size, especially when the seat of cystic and hemorrhagic dilatations, yet occasionally scirrhous carcinomas are formed of such small size that it may be impossible to palpate them. In such cases as this, careless autopsies may fail to explain, or may explain incorrectly, the origin of the metastases found. The greater part of the growth in the thyroid results from fusion of secondary growths, rather than from a process of infiltration. Histologic diagnosis is particularly difficult, not only between sarcoma, carcinoma, and endothelioma, but especially between carcinoma and benign adenomas. Medullary carcinoma is the most frequent form of carcinoma, although adeno-carcinoma and cylindrical-celled forms are not infrequent. Associated with papilliferous tendencies cyst formation often occurs, resulting in a growth described as *cystadenoma papilliferum malignum seu carcinomatodes.* The cases of scirrhus, in Erhardt's report, number but six, the growth in them being chiefly at the periphery, while the centre had been replaced by a mass of scar tissue. The rare instances of primary squamous-celled carcinoma are probably to be explained as originating from misplaced embryonal remnants rather than as growths due to metaplasia. The sarcomas are composed chiefly of round and of spindle cells. They are rarely encapsulated. Generally they infiltrate the gland diffusely; sometimes they entirely replace its structures. Much less frequent are cavernous and giant-cell sarcomas, while there are a few instances of osteoplastic sarcoma. Tumors of the type of the peritheliomas, with cells radiating about vascular channels, are not uncommon, the simpler endotheliomas being much less frequent. While a case of primary melanosarcoma exists in the literature, the report of this case makes it seem probable that the growth was really secondary. Other malignant tumors described are chondro-osteoid sarcoma and teratoma malignum.

Secondary tumors of the thyroid are but rarely found. Some of these are of vascular implantation, and some owe their origin to an extension from neighboring growths, especially of the larynx and œsophagus.

Extension and Metastasis.—After the growth once penetrates the capsule it usually grows rapidly and involves the surrounding tissues extensively, often fusing with the regional lymph-gland metastases. Often the trachea is infiltrated, twenty-two such cases being reported in the series. In these the growth took place either by direct extension from the thyroid or by transference by way of the tracheal lymphatics. The œsophagus is often also involved, as also is the sternum. While the large veins of the neck are often invaded and plugged by the growth, the arteries seldom are. The vagus and sympathetic usually resist invasion, but the recurrent laryngeal is often involved. Invasion of the muscles and other tissues of the neck is not particularly common. Metastasis usually takes place early in all

FIG. 4715.—Secondary Carcinoma Nodule in Lung, Secondary to Carcinoma of the Thyroid shown in the Preceding Drawing. Illustrates tendency of secondary tumors to approach normal gland in structure.

varieties of sarcoma and carcinoma except the papilliferous cystadenomas. Of 94 bodies thoroughly examined but 14 were devoid of metastases. Of 46 carcinomas 23 had metastases by the blood stream alone, 9 by the lymphatics alone, and in 14 the metastasis was by way of both these channels. Of 34 sarcomas the transmission was by the blood in 24, in 7 by lymph alone, and in 3 by both. This great relative frequency of dissemination of the carcinomas by way of the blood is explained by the great vascularity of the gland, the early invasion of the large veins of the neck, and the resistance to lymphatic transportation that the capsule of the gland seems to offer. Of 131 carcinomas and 107 sarcomas metastases were found in the lymph glands in 49 of the former and 18 of the latter. Erhardt has made an extensive study of the lymphatic system of the thyroid, both in health and in relation to tumor transportation, and as there seems to be no other accessible study of a similar nature, I will give here the main features.

The *lymphatics* of the lateral lobes anastomose to a slight extent, much less so than has been generally supposed. This fact explains the relative infrequency of transportation of carcinoma from lobe to lobe, in contrast to the frequent direct extension of sarcomas. The greater part of the lymphatics are collected into a few large stems on the lateral and posterior sides of the gland, where what appear to be lymph reservoirs containing large quantities of colloid can be found. These vessels pass to the glands about the large vessels in the neck, which are first and almost constantly involved when there is lymphatic dissemination. Then follows infection of the inferior and deep cervical glands below and behind the clavicles These are in turn connected with the axillary and mediastinal glands, which are accordingly next involved. The isthmus is connected chiefly with the glands lying between the œsophagus and the larynx, whose involvement is important because of the serious pressure effects that are certain to result. These glands communicate with a retro-œsophageal plexus. There are some lymph vessels that pass directly from the upper poles of the lateral lobes to the submaxillary and sublingual glands, which are occasionally infected in early stages. Similar direct branches pass from the lower poles to the mediastinal glands. After the usual routes have become plugged with tumor growth the flow may pass in any conceivable way, with corresponding location of the metastases.

In the following table is shown the order of frequency of location of the vascular metastases.

	Carcinoma.	Sarcoma.
Lungs	66	63
Bones	43	23
Liver	21	15
Kidney	13	7
Pleura	10	6
Brain	7	5
Scattering	7	6

The great frequency of osseous metastasis in thyroid tumors, similarly to what occurs in the prostate, is well known. At the same time, no satisfactory explanation seems to be forthcoming. Such metastases are most often located near the epiphyses, and often lead to spontaneous fracture, which differs from that resulting from primary bone tumor in that sometimes the bone reunites because of the formation of abundant osteophytes. Iodine has been found in the bone metastases. A table of the frequency of involvement of the bones is of interest.

Skull	30	Humerus	10
Inferior maxilla	30	Pelvis	8
Sternum	18	Scapula	4
Vertebræ	11	Malar	2
Ribs	11	Palate	1
Femur	10	Clavicle	1

Symptomatology.—The mere fact that a thyroid increases rapidly in size is hardly an indication of the presence of a malignant growth, since such an increase in size so often happens either in goitrous or in non-goitrous glands. The relative frequency of non malignant enlargements, as compared with those which are malignant, is apt to divert suspicion, particularly when goitre previously exists. Probably the most important of the symptoms is immovability of the gland during the act of swallowing, which was noted in forty per cent. of the collected cases. However, this symptom is sometimes present in benign goitre, and, since in cancer it usually is the result of extracapsular extension of the growth, binding it to the neck tissues, it is not, as a rule, a very early symptom. Dyspnœa also is of slight value, because the goitre that commonly precedes it usually causes this symptom to be wrongly attributed, although in the case of a malignant growth the dyspnœa is particularly severe. Deformity of the larynx and trachea may be observed by laryngoscopic examination when the dyspnœa is not too great. Occasionally hæmoptysis results from intratracheal extension. Obstruction of the œsophagus is sometimes severe, with symptoms much the same as in stricture from other causes; the obstruction is usually located about 20 cm. below the teeth, and phlegmon may result from the tissues becoming infected. The superficial veins are prone to be more distended than in simple goitre, and sometimes they may be palpated when filled by tumor growth, from which metastases with their resulting symptoms may develop. Occlusion of the carotid, with the consequent loss of pulsation, is of significance as regards malignancy, but still more so is the direct entrance of the vessel into the tumor mass, a condition which can be made out without difficulty. Paralysis of the recurrent laryngeal is of great importance, for although it may occur in goitre, it does so rarely. Of twenty cases of this complication, in seventeen the involvement was unilateral, in three bilateral. The vagus usually escapes and the instances of tachycardia and arrhythmia from this cause are rare. The sympathetic is involved a little more often than the vagus; it is indicated by a pin-point pupil, a narrowed palpebral opening, and local vascular dilatation with local sweating and local heat. Only in the latest stages does involvement of the hypoglossal and spinal accessory occur, with paralysis of the tongue and dropping of the shoulder. Neuralgic pains, that radiate to the ear, shoulder, and occiput, often develop in the growth, and sometimes at quite an early stage. Fever of mild grade, independent of complications, is not rare. It is important to note that cachexia is not a common accompaniment of the disease; it was observed in only twenty out of one hundred and fifty cases. The destruction of the gland does not lead to manifestations of cachexia strumipriva, partly because of the slowness of the process, but probably more because the tumor is able to form colloid itself. In six reported cases the features of exophthalmic goitre were present, and in three of these they were relieved by operation.

The average duration is about two years, with no great differences between carcinoma and sarcoma, although the most acute growths are usually sarcomas, the most chronic being the scirrhous carcinomas. Death rarely results from cachexia because of the location of the growth, which most often kills by involvement of the air passages, (either from asphyxia or from pneumonia). The asphyxia may result from œdema of the glottis, from kinking of the trachea, or from sudden swelling of the tumor through hemorrhage or congestion. Fatal hemorrhage is rare; the blood may escape into the air passages or even into the tissues.

Operative treatment is difficult, first because suspicion of malignancy in the goitrous neck comes late, and also because of the respiratory complications that are usually present at the time operation is sought. Narcosis is usually extremely dangerous, and Erhardt advises that operation be begun under local anæsthesia, and that chloroform be given if the operation becomes too painful. In the early stages it may be possible to enucleate the entire gland with success, but this is probably done oftenest when the growth is in a goitre that has not shown its malignant change clinically. Of course, thorough clearing out of the neck is the only operation possible when the capsule has been penetrated and the glands are involved. The cachexia strumipriva is to be combated by thyroid medication as the lesser of the two evils. Of 68 partial thyroidectomies (unilateral) performed during the past ten years 6 were fatal immediately after the operation—10 per cent. against 2.88 per cent. in benign goitre. Of 17 thyroidectomies involving resection of surrounding structures, including trachea or œsophagus, 5 were fatal. The results are much better now than in the previous decade. In several instances the patients remained free from a recurrence of the growth for a period of several years. In one case, according to the report, the recurrence took place as late as eight years after the removal of the original growth. Recurring growths are usually diffusely infiltrating and inoperable, frequently requiring tracheotomy.

Mixed Malignant Tumors of the Thyroid.—In reporting a case of a malignant tumor in the thyroid of a dog in 1901, which was remarkable in that the primary growth

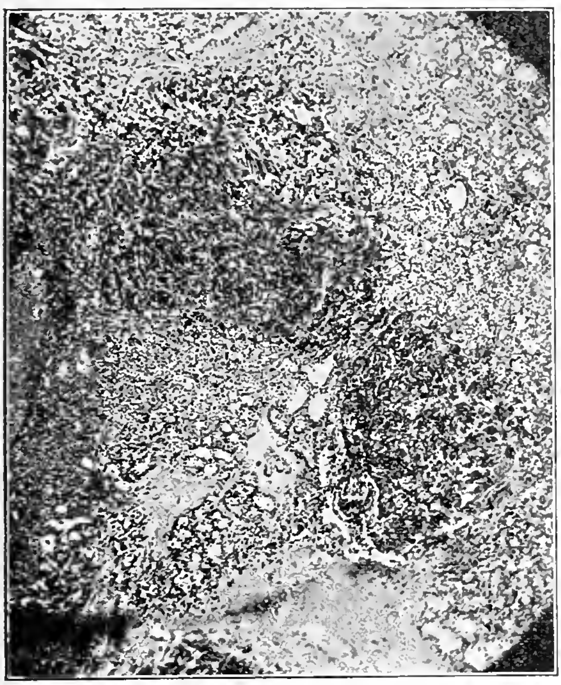

Fig. 4716.—Primary Mixed Tumor (sarcoma and carcinoma) of the Thyroid. The sarcomatous tissue is seen extending obliquely across the section.

consisted of a mixture of sarcomatous and carcinomatous elements, and had produced metastases of each kind of tumor tissue, as well as of the mixed variety, I searched the literature for other instances of mixed malignant tumors. I was able to find only two such instances, both of which were in the thyroid. Since that time a similar case has been reported by Woolley, and another by Leo Loeb, in each case in the thyroid. That all the existing instances in which a primary tumor presented a mixture of carcinoma and sarcoma were thyroid tumors, in the face of the infrequency of malignant tumors of the thyroid, is certainly of some significance, but it has not yet been determined what the significance is.

Metastasis of normal thyroid tissue and of benign thyroid neoplasms has been reported in a number of instances. This apparent exception to the rules of tumor- and tissue-growth would seem to be best explained, in the light of the latest studies, as due entirely to misinterpretation of histological pictures or to inaccurately studied cases. An example is the report of Oderfeld and Steinhaus published as recently as in 1901. This report concerned an instance in which a growth had developed in the left frontal bone, having the structure of normal thyroid gland, and it did not recur after removal. In the absence of any evidence of disease in the thyroid itself this growth was believed by the writers to be the result of metastasis of normal thyroid tissue which had proliferated in its new location as does a thyroid graft. A similar case had been reported by Riedel. In less than two years the authors named above were obliged to report an entirely different explanation. The patient had died in the mean time with multiple metastases, all of which had a structure that resembled normal thyroid. The thyroid itself showed no growth except a small encapsulated nodule, which also was of the structure of normal thyroid. They were obliged to conclude that, after all, their case was one of carcinoma of the thyroid with metastases, remarkable chiefly for the resemblance of the structure of the tumor to that of the gland. A study of many cases of thyroid carcinoma shows that the metastases have a decided tendency—which is particularly true of adenocarcinoma—to reproduce the structure of normal thyroid-gland follicles. It is highly probable that the above-mentioned facts are sufficient to explain the supposed instances of transportation of normal gland tissue or adenomas, and that it is safe to assume that when any structure of the thyroid produces metastases it is to be considered *prima facie* evidence of the malignancy of that structure.

Tumors of the thyroid in lower animals are by no means infrequent, especially in dogs, in which goitre is common. They have also been described in horses. They seem to differ not at all from those observed in man. Of the five sarcocarcinomas reported, one was in a dog, and another, that of Loeb, was in a white rat. It may be recalled that Loeb's work on the transplantation of tumors was done with a thyroid sarcoma from a rat.

TINEAS, THE.—There are included under the general term of *Tinea* several diseases of the skin, both of the hairy and the non-hairy parts, caused by the parasitic action of various kinds of fungi belonging to the order of *Hyphomycetes* or mould fungi. These fungi have an affinity for the keratinized portions of the skin and its appendages—hair, nails, and epidermis. They attack these structures in man and some of the lower animals (horses, dogs, cats, birds), and infection in the former can often be traced to the latter source.

Although these moulds thrive best upon the surface of the skin, certain varieties sometimes penetrate beyond the superficial horny structures into the corium or subcutaneous tissues, causing the so-called *kerion* and *hyphomycetic granulomata.*

In all of the various diseases caused by these fungi they may be readily detected by the following procedure: A small piece of crust, scales, hair, or pus is placed in a

FIG. 4717.—Section of Favus scutulum, showing Spores and Mycelium of the Fungus, Achorion Schönleinii. (Bausch and Lomb one-eighth inch objective, one inch eyepiece.)

few drops of liquor potassii or a week solution of caustic soda upon a glass slide and allowed to remain for a few moments; a cover glass is then pressed gently over it. A one-seventh objective and low eyepiece will disclose the conidium or spores and the mycelium or threads, which vary in their size, shape, and arrangement according to the variety of the fungus to which they may belong. The spores are small, round or oval, bodies; and the mycelia long, sharply defined, narrow tubes which fork or branch in various directions

TINEA FAVOSA, or favus, is a contagious and very chronic disease of the hairy and non-hairy parts, due to

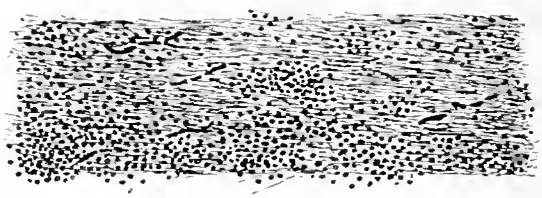

FIG. 4718.—Microsporon Audouini (small-spore fungus) in Hair. (Engman.)

the action of the fungus, Achorion Schönleinii, which causes the formation of cup-shaped yellow crusts about the hairs, and subsequent atrophy and baldness of the part.

The most common location for favus is upon the scalp, but any portion of the integument may be attacked. The nails especially are not infrequently involved by secondary inoculation from the scalp. The disease is rarely contracted after childhood, and is said to be more frequent in males. It is usually seen in this country (United States of America) among the poorer classes of foreigners, especially in Polish, Russian, German, and Italian children.

The fungus gains access to the scalp generally through direct contagion from another child, or from one of the pet, domestic animals, and shows its presence there by causing a superficial, slightly red, scaly patch, which slowly changes its aspect until it presents, at several of the follicular openings, a small yellow point pierced in its centre by a hair. These points gradually increase in size and develop into the "cups," crusts, or scutula, characteristic of the disease. They vary in size, but at an early stage show the scooped-out or cup-shape, which is produced by the luxuriant growth of the fungus at the mouth of the follicle and the rapid increase and piling up of its elements and tissue débris at the peripheral portion in a uniformly concentric manner. The convex or under surface of the scutula is rather firmly attached to the skin, at the mouths of the follicles, and when removed discloses an oozing, slightly excavated and reddened surface. If the crusts are allowed to remain for a sufficient length of time the surface upon which they rest becomes atrophic, white, and permanently bald. The yellow color of the crusts may, from the admixture of foreign material, become correspondingly modified. As the disease progresses new foci of infection may appear or the initial patch may spread peripherally, and as the scutula increase in size and numbers, they join each other, producing diffuse, "mortar-like masses," often extending over a large surface. When this occurs a peculiar mouse-nest odor is apparent.

The hairs are involved very early in the disease; their nutrition is interfered with by the mechanical influence of the mass in the follicle, and by the direct parasitic action of the fungus which grows upon the shaft and in the medulla, with the result that the hairs become lustreless, friable, brittle, and break off or fall out. When the stumps are of sufficient length a frosted or peculiar powdered effect is often seen in a reflected light, due to the access of air into the split up shaft.

The disease is generally slow in its progress, and varies in different climates and different individuals in the rapidity of its extension and growth The fungus, having gained access to the follicle, increases proportionately to the fertility of the soil, and produces the favus scutulum, varying in size from a pea to a silver dime, the presence of which by its pressure and probably by the toxicity of the organism causes a mild inflammation. This inflammation and the mechanical pressure of the scutulum, if long continued, produce an atrophy of the tissues, the contraction of which loosens the crust and it is then either knocked or cast off, leaving a pinkish-white atrophic surface, free from hair. As this process of recent infection of new and atrophy of old infected follicles is continuously going on, a patch may present crusts in various stages of evolution, with atrophy between them.

Favus of the non-hairy parts presents the same essential characteristics, in the lanugo hair follicles, as upon the scalp, except in certain cases in which a special variety of the fungus or a peculiar condition of the soil causes alterations similar in appearance to those of tinea circinata (favus à lésions trichophytoïdes). In neglected cases great yellow masses may be scattered generally over the surface of the body.

Favus of the nails (Onychomycosis favosa) may occur in two forms: in one a scutulum is formed in the deep cells of the nail, and is distinguished as a small yellow mass through the clear nail substance above it; in the other variety the nail plate is lustreless, fissured, split, and raised from its bed, but the microscope is necessary to confirm the diagnosis.

If the characteristics of favus are kept in mind the diagnosis is not difficult, except in atypical forms, when it is necessary to demonstrate the fungus in the scales in order to differentiate the condition from certain types of eczema.

The distinguishing microscopical characteristics of the favus fungus are the predominance and great variety as to the size of the spores, the short and jointed appearance of the mycelia, and the ease with which they break up into single cells (Kaposi).

Prognosis.—Favus is one of the most difficult of scalp diseases to cure, and consequently a very guarded prognosis must be given; months and often years are necessary to effect a cure.

Treatment.—The indications for treatment are to remove the crusts with a sulphur salve or carbolized oil, to resort next to epilation, and then immediately afterward to apply some parasiticide, which should be rubbed vigorously into the parts. The methods of treatment and

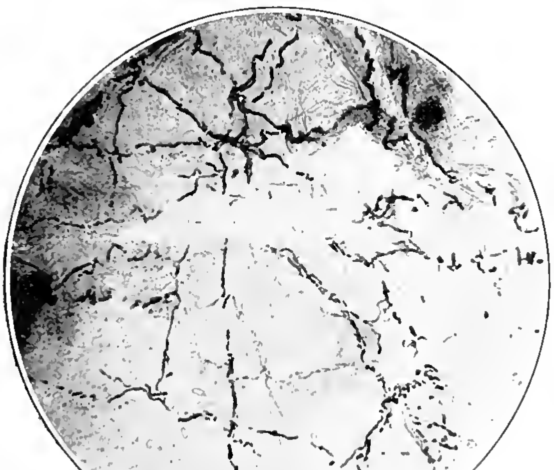

FIG. 4719.—Microsporon Audouini (small-spore fungus) in Horny Layer. (Eyepiece, three-fourth inch; objective, one-twelfth inch; oil immersion.)

agents recommended are innumerable. The hairs should be epilated well beyond the diseased area, and, whatever remedy be selected, it should be applied immediately. George T. Jackson has had good results in both ringworm and favus with iodine (one drachm of the crystals rubbed up in an ounce of goose grease). The writer has been encouraged by the results obtained from the thor-

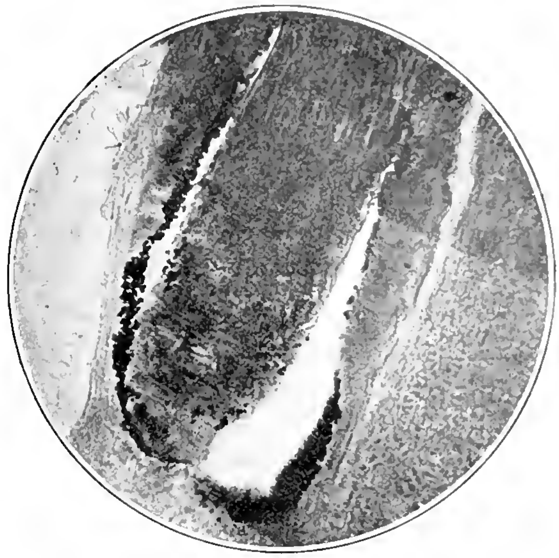

FIG. 4720. Microsporon Audouini (small-spore fungus) in the Follicle and Hair. (Eyepiece, two inches; objective, one-eighth inch.)

ough application of equal parts of trikresol and alcohol after epilation. Sulphur, chrysarobin, pyrogallic acid, tar, and numerous other parasiticides have their advocates, however. Many of them will prove efficacious in conjunction with epilation, patience, and perseverance. The most encouraging remedy of all is probably that of radiotherapy. The patch or patches should be exposed to a tube of low vacuum for from ten to twenty minutes two or three times a week, until the hairs fall out. This procedure often effects a cure. The healthy scalp should be protected by lead foil. Upon the glabrous skin favus should be treated as ringworm (Tinea circinata).

TINEA TRICHOPHYTINA OR RINGWORM.—The presence of the ringworm fungi excites upon the skin several clinical types of disease, which vary in their symptoms according to the locality attacked and the variety of the fungus concerned.

Formerly the ringworm fungi were thought to be identical until Sabouraud demonstrated (and his observations have in the main been confirmed) that they should be divided into two groups—a small-spore (*Microsporon Audouini*) and a large-spore fungus (*Megalosporon*). The latter he subdivides into *Megalosporon ectothrix* and *Megalosporon endothrix*, according to whether its elements lie outside (*ectothrix*) or in the shaft of the hair (*endothrix*), which is believed by many to be a fanciful division, as these two forms seem to be "a question of soil rather than of origin" (Crocker).

The small-spore form chiefly attacks the scalp of children, and is responsible for the majority of the resistant cases of ringworm in them. Upon microscopical examination the spores are seen to have a lack of any particular arrangement, being in irregular groups or swarms, which is characteristic. Each spore is separate from the other, and they are located outside the shaft of the hair, with a few thin, curved, branching mycelia in the medulla.

The large-spore form causes a small percentage of scalp ringworm, but is the one most commonly found in that of the beard, glabrous skin, and nails. The spores in this variety are arranged in chains with short-jointed mycelium here and there; these elements being in more or less profusion either in or outside the shaft or they may occupy both localites—an endo ectothrix.

Wherever the large-spore fungus is found, especially the ectothrix variety, there are more objective signs of inflammation. Sabouraud affirms that the ectothrix is

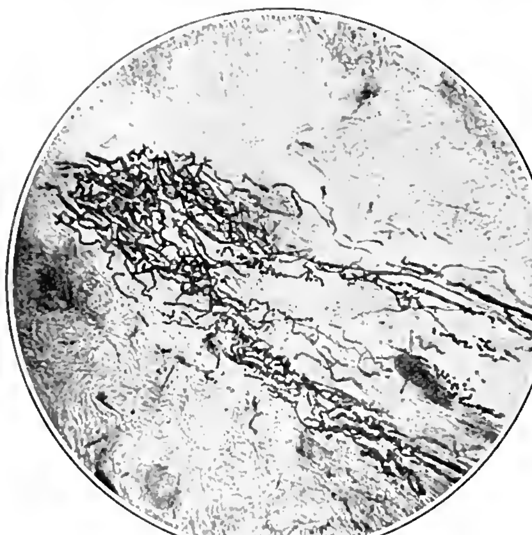

FIG. 4721. Microsporon Audouini (small-spore fungus) in Tissue about Follicle. (Eyepiece, one inch; objective, one-twelfth inch; oil immersion.)

always of animal origin, and is the cause of all pustular ringworms; others, however, have found the microsporon in similar conditions.

If the arrangement and location of the spores in the different forms be remembered, one can upon microscopical examination readily determine the variety to which they belong.

Trichophytosis is contagious, the fungus being conveyed by direct contact or through the media of toilet articles, wearing apparel, bed linen, etc. It is less frequent after the age of fifty, and some individuals are probably more susceptible than others. In children the scalp and in adults the glabrous skin and beard are the regions most frequently involved.

TINEA TONSURANS OR RINGWORM OF THE SCALP occurs almost exclusively before the age of fifteen years.

Since the investigations of Sabouraud and others it is necessary to treat the clinical aspects of scalp ringworm especially from a pathological standpoint, according to the variety of the invading fungus.

Microsporon Ringworm of the Scalp.—The small-spore fungus is accountable for from eighty-five to ninety per cent. of all scalp ringworms, and occurs exclusively in children. It is generally seen as one or several round or oval bald-looking patches of a slaty, dull gray color, their size dependent upon the length of time they have existed, as they begin from small points and spread peripherally. Various bizarre or gyrate outlines may be described if several patches coalesce. The infected surface, which may be more or less thickened, is covered by fine whitish scales, and the hairs are found upon close inspection to be twisted, bent, or broken off close to the scalp. This circumstance, coupled with the fact that a fine white sheath extends a short distance upon the shaft, gives the patch the appearance of being bald. When a hair is pulled it readily breaks, showing the disorganizing effect of the fungus upon it. Under the microscope the hair is seen to be frayed at the ends, and the white sheath to be composed of the fungus elements. In but few cases are there any symptoms of active inflammation.

Megalosporon Endothrix of the Scalp.—The endothrix fungus is divided by Sabouraud into two subdivisions: one with mycelium which breaks easily ("fragile") and the other with a more resistant mycelium ("resistant"). These varieties cause an alopecia, which is often quite similar in appearance to alopecia areata. There may be one or several smooth bald patches disseminated over the scalp, with a few illy-nourished hairs scattered over it, and numerous "black dots" here and there, which upon extraction prove to be broken and disorganized hairs. The patches are irregular in shape, and in some cases are pityriasic. In this form of ringworm there may be scattered groups of a few broken hairs upon a scaly, scurfy scalp.

"Black-dot ringworm," "disseminated ringworm," "bald Tinea tonsurans" are terms formerly used by English writers to designate this form.

Megalosporon Ectothrix of the Scalp.—The ectothrix always causes more inflammatory symptoms than do the other types. The infection begins as a red, scaly ring with a distinct border composed of papules, vesicles, or, later, pustules, the hairs becoming disorganized and broken as the disease progresses. In many cases the fungus penetrates deeply into the follicle and produces marked inflammation with suppuration, forming a fluctuating mass, from which pus oozes at the openings of the follicles. The condition thus caused is known as *Kerion.* Several English observers have seen the microsporon cause the same process.

Granuloma trichophyticum of Majocchi is analogous to kerion; so also is *hyphomycetic granuloma* (Schamberg), which may simulate a malignant growth. *Conglomerate pustular folliculitis* or *agminate folliculitis* consists of a circumscribed, highly inflamed patch, occurring generally upon the hand or arm, at the follicular openings of which is a pustule or an oozing point from which pus can be expressed—a pus which contains double-contoured spheres, the spores of the Trichophyton ectothrix.

The diagnosis of scalp ringworm is made by the broken hairs and the microscopical demonstration of the fungus elements.

The prognosis as to ultimate cure is good, but from three months to a year is a conservative estimate as to the time necessary for the cure, especially in the microsporon type. Permanent baldness often remains at the site of kerion.

TINEA CIRCINATA, TINEA CORPORIS, OR RINGWORM OF THE BODY are the terms applied to the invasion of the non-hairy skin by the trichophyton fungus, all varieties

FIG. 4722.—Megalosporon ectothrix (large-spore fungus) in Hair. (Eyepiece, three-quarter inch; objective, one-twelfth inch; oil immersion.)

of which cause at the beginning of infection a circular scaly pink patch that spreads peripherally with a pinkish border, and clears up or involutes in the central portion.

leaving a faintly yellowish tinge in its wake, thus forming a ring. The border of the ring may be minutely papular or vesicular.

The rings caused by *microsporon* are small, seldom larger than a silver quarter, and are generally seen upon the exposed parts in children with ringworm of the scalp.

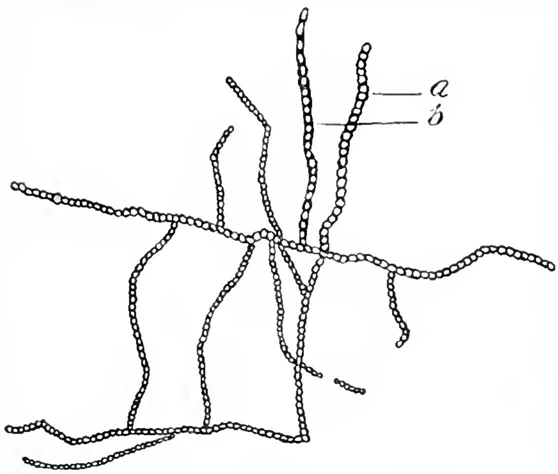

FIG. 4723.—Megalosporon Ectothrix (large-spore fungus) from Nail Scrapings. *a* and *b*, Filaments of very large spores. (Engman.)

Not infrequently in this variety small scaly, reddish plaques are seen which do not undergo central involution to form rings.

The rings caused by *megalosporon* are large, often attaining several inches in diameter; they are scaly; the border may be papular, vesicular, or crusted; all the symptoms are more inflammatory than in the former type. If several points of infection occur close together, the rings may meet by peripheral extension, forming various gyrate figures.

When the infection occurs in the genito-crural or axillary regions, where the heat and moisture of the part favor the growth of the organism and a more inflammatory reaction, there ensues a condition which was formerly called "eczema marginatum," and can often be differentiated from certain forms of eczema only by the demonstration of the fungi.

The diagnosis of ringworm of the body is difficult only when there are numerous foci scattered over the body, and when the patches fail to form rings, in which event microscopical aid is necessary to differentiate it from eczema seborrhoicum of Unna and from certain analogous forms of that disease.

The disease in all its various phases is readily amenable to treatment.

TINEA BARBÆ, TINEA SYCOSIS, BARBER'S ITCH, is a folliculitis of the hairy portion of the face caused by the *Trichophyton Megalosporon Ectothrix*. The disease is generally contracted in barber shops, the fungus being most probably conveyed by the shaving brush or "pinchers" used by barbers for extracting "ingrowing hairs."

The earliest symptoms consist of one or more scaly spots or rings of a rather inflammatory nature. Scattered on or about the border of the patch are several hard, raised papules or pustules, pierced by a hair. The subsequent increase of symptoms depends upon the soil, and upon neglect or improper treatment; more papules and pustules develop, the hairs are loosened and may easily be plucked out. The part burns and itches, and is inflamed and swollen in appearance. By the massing together of a number of infected follicles, pea- to nut-sized nodules form, the surface of which becomes crusted. When the crust is removed a raw, excoriated surface is exposed, dotted by oozing points. This appearance has been compared to the cut surface of a fig; hence the term sycosis (σῦκον, a fig). There is only moderate tenderness or pain about these lesions.

The diagnosis of Tinea barbæ is readily made by the ring, by the nodules, and by painless extraction of the hairs; in mild and atypical cases it may be easily confounded with coccogenic sycosis ("non-parasitic"). The latter has not the deep lesions or lumpiness, is not so rapid in its progress, and the hairs are not loose and are painful to extract.

TINEA UNGUIUM, ONYCHOMYCOSIS TRICHOPHYTINA, RINGWORM OF THE NAILS, is due to the Megalosporon ectothrix. It is usually a secondary auto-inoculation from ringworm elsewhere, causing a splitting up of the nail plate, rendering it brittle, dull, yellowish, ridged or striated transversely or longitudinally; finally, the separation of the nail plate from the bed may occur. One or more nails may be involved, but seldom symmetrically.

A diagnosis from various other nail diseases which present similar symptoms can be made only by microscopical examination of the nail scrapings (Fig. 4723).

The condition is exceedingly difficult to treat successfully, and may last for years.

TINEA IMBRICATA or TOKELAU RINGWORM is a form of ringworm which occurs in the tropics; it is characterized by the formation of large concentric rings of scales, involving a large part of the body surface, but rarely attacking the hair or follicles. It is probably due to a special variety of the large-spore trichophyton fungus.

TINEA VERSICOLOR, PITYRIASIS VERSICOLOR, CHROMOPHYTOSIS is a parasitic disease caused by the *Microsporon furfur*, a fungus, and characterized by variously sized and shaped pityriasic patches of a yellowish, fawn color, which occur most frequently upon the trunk. The disease may be said to be confined to the trunk, but it at times is seen upon the neck, arms, thighs, or other parts. Allen claims that the hairs of the pubic region often conceal a patch that may remain as a focus for subsequent reinfection. The patches begin as small, roundish, yellow, or light-brownish points, which increase in size very slowly by peripheral extension or by the coalescence of several points of infection, thus forming variously sized patches; sometimes one patch may involve a large area of skin, possibly more or less of the whole trunk. The borders of the patches are sharply defined, almost imperceptibly raised, and the surface, especially near the periphery, is slightly scaly, the scales being fine and of a dirty white color. In the dark-skinned races the diseased areas are darker than the surrounding skin. In very fair individuals it is not uncommon to find a tinge of red added to the fawn color of the patches, showing through the yellow, especially in hot sultry weather.

The infection progresses very slowly, and shows no tendency to self-limitation. The fungus, the Microsporon furfur, is the sole cause of the condition, and is

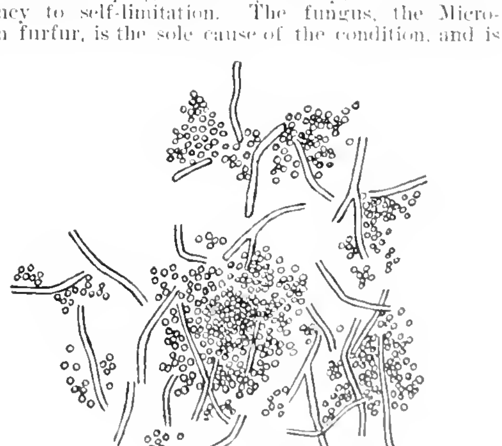

FIG. 4724. Microsporon furfur, Fungus of Tinea versicolor. Spores and mycelium. (Diagrammatic.)

easily detected by scraping off a few of the scales and examining them in liquor potassii as before described. It is readily differentiated from the other fungi by the large size of the conidia or spores and by their tendency to occur in groups or masses over the field; the mycelia are fine and interlace between these groups. The Microsporon furfur grows luxuriantly in the upper layers of the epidermis, causing no appreciable irritation, and produces by its strongly refractile spores the yellowish color of the infected regions. It is supposed to have greater affinity for a moist skin; it is therefore found most frequently in those who perspire freely. Perfectly healthy adults are attacked as well as the delicate. It is exceedingly rare in children. The disease is contagious, but mildly so, as some special condition of the epidermis besides moisture is necessary for the growth of the organism.

In all suspected cases the scales should be examined for the fungus. Mild parasitic applications cure an attack. Of these the most elegant and cleanly is a saturated aqueous solution of hyposulphite of soda, applied night and morning after a soap and water bath. A cream of ten-per-cent. sulphur precipitate in Unguentum aquæ rosarum is equally efficacious. Various other parasitic ointments and lotions are used. The attack is easily cured, but when once a person has become susceptible recurrence is the rule; therefore each relapsing spot should at once be destroyed, with any of the agents mentioned; care also being given to the sterilization of wearing apparel and articles of the bath.

Treatment of the Various Forms of Tinea.—The cure of all the types of ringworm depends upon the efficacy with which the parasiticides are brought into contact with the offending organism. This is easily enough accomplished upon the glabrous skin but is quite difficult when the hair follicles are infected. In the latter event it is recommended to extract the hair by epilation, which often proves useless, as the hairs are frequently so badly disorganized that the least traction breaks them off close to the scalp, or just within the follicle. This, however, is not true in ringworm of the beard, where the disease is due to the ectothrix variety, with the formation of pus and the subsequent loosening of the hair. In the infection of the scalp in children, by the microsporon fungus, which disorganizes but does not loosen the hair, it is probably better to "shingle the head than to spend useless time and trouble breaking the hairs by epilation. Epilation by means of the *x*-rays is not indicated here as in favus, for fear that permanent baldness may ensue. The latter disease (favus) frequently produces permanent baldness independently of epilation, while it never occurs in ringworm except in kerion.

Chrysarobin, pyrogallic acid, oleate of mercury, iodine, salicylic acid, sulphur—in fact, all antiparasitic agents, have been used in ringworm of the scalp with more or less success. Whatever remedy be selected it is necessary that it be applied thoroughly and often, and in a medium which is capable of being manipulated into the follicle. It is also necessary to employ the agent in sufficient strength to kill the parasite and cause a not too violent reaction of the skin. Of all these agents chrysarobin, in the following combination of Unna's, has, in the writer's hands, proved the most efficacious: Chrysarobin, 2 parts; ichthyol, 5 parts; salicylic acid, 5 parts; and vaseline, 88 parts. This is applied to the whole scalp (after the hair has been cut as short as possible) twice daily, with a soft tooth brush. A cloth cap is then fastened to the head by a bandage passed along the hair line; this prevents the chrysarobin from getting upon the smooth skin or in the eyes. The latter accident should be carefully avoided. The scalp will show irritation from this treatment in from two to four days. Then the chrysarobin salve should be washed off and a soothing cream or ointment applied until all irritation has subsided and the reduced or hardened epidermis scales off. This procedure should be repeated for several courses, until the hair again grows to sufficient length to show whether or not the fungus has been entirely destroyed. Frequent microscopical examinations are a great assistance in watching the effects of the treatment. The chrysarobin discolors the skin and hair and is an heroic procedure. In young girls, and when the patient cannot be carefully observed, less heroic measures are advisable. In all cases in which the sacrifice of the hair is not too great it should be closely cut, and some weak parasiticide applied to the whole scalp, while the patches themselves may be treated more vigorously. A very good procedure is to apply to the entire scalp a weak sulphur cream and attack the patches with one of the stronger parasiticides previously mentioned. Trikresol, lately introduced by MacGowan, is a most valuable remedy. The patches should be first rendered free of fat and débris by washing with ether or benzin. A mixture of equal parts of trikresol and alcohol is then well rubbed, with a cotton swab, into and beyond the patch. This applicaion will cause some desquamation, which will last for several days, when the remedy may be again applied; some mild antiseptic cream being used in the mean time. Precipitated or sublimed sulphur, in the proportion of from twelve to fifteen per cent. in lard or vaseline, is slow but efficacious. It is well to remember that it is useless to continue applying a remedy after it has caused thickening of the epidermis, and therefore more obstruction in the mouths of the follicles, thus protecting the fungus. It is better to wait and assist the desquamation of the epidermis by the use of a mildly antiparasitic salve before proceeding.

Ringworm of the body is best treated by means of pastes, to which is added a parasiticide. The pastes adhere to the skin, and are not easily rubbed off. The best of these is one made of equal parts of oxide of zinc, starch, vaseline, and lanolin. To this may be added either sulphur (from six to twelve per cent.) or ammoniated mercury (four to six per cent.). Taylor recommends one to three grains of mercuric bichloride to an ounce of the compound tincture of benzoin. Resorcin, salicylic acid, ichthyol, and preparations of tar are all efficacious in salves, pastes, or lotions.

"Eczema marginatum" is, for the reasons already given, the most difficult of the so-called body ringworms to cure. In this affection pastes often prove irritating; the application of salves, dusted over with talcum powder, is more agreeable. The itching and consequent rubbing and excoriation are elements to be dealt with in this locality; therefore the use of an antipruritic, like carbolic acid, is necessary. The writer has been pleased with the following: Carbolic acid, gtt. v.; precipitated sulphur, gr. xx.; balsam of Peru, gtt. xx.; vaseline, ℥ v.; lanolin, ℥ iij. Lotions, unless the case is very mild, do not act well in this locality.

Tinea barbæ in the mild form is readily cured by the application of any of the parasiticides mentioned. In severe cases the crusts should be removed with carbolized or salicylated oil or vaseline; the diseased hairs should be epilated and the beard shaved, immediately after which the remedy is rubbed in. Sulphur, five to ten per cent. in vaseline, or in equal parts of lanolin and vaseline, is generally useful. Xeroform, five per cent. in olive oil, has proved valuable in the writer's experience.

In Tinea unguium the nail, after being scraped, should be soaked in a hot alkaline solution, and the parasitic salve rubbed in; then some of the salve should be spread upon cloth and bandaged on, or held in place by a finger cot. Unna applies, after the scraping, a solution of bichloride of mercury, in flexible collodion thinned with ether (bichloride of mercury, gr. i.–iv.; ether, ℥ ij.; flexible collodion, ℥ vi.). *Martin F. Engman.*

TINNITUS AURIUM.—DEFINITION.—Any subjective noise, heard in one or both ears, as the result of some abnormal condition somewhere in the body.

CAUSES.—Anything which irritates the nervous mechanism of hearing, in any part, from the cortex of the brain to the cochlear hair cells. Tinnitus has been noted as an *aura epileptica* (cerebral irritation); at the onset of an attack of *syncope* (cerebral anæmia); and at the time of an attack of cerebral hemorrhage (general cranial hyperæmia). It also occurs as the result of poisoning by certain drugs (quinine, salicylic acid). The precise physiology of this action is not clear, but it is probably due to cerebral irritation, since it can be readily controlled by the administration of bromides. Tinnitus is also observed in meningitis. This may depend upon irritation of the auditory nerve in its course.

As commonly seen, however, tinnitus is due to some form of ear disease, and some of these cases present perhaps the most perplexing problems which the whole range of otology can offer. For it is a matter of common observation that a moderate degree of deafness may pass unnoticed for years, and finally be discovered, as it were by accident, by a patient's friends. Tinnitus, however, never fails to be a matter for complaint, causing as it does a degree of discomfort always considerable, and being often of grave danger to the patient's bodily and mental health. It has been claimed that some suicides have been caused by loud and persistent tinnitus, but the writer has not been able to find any reported cases. It is, however, almost certain that in persons predisposed to mental disease, tinnitus has led to auditory hallucinations, and thus has acted as the determining cause of an attack of insanity.

According to Sexton, fifty per cent. of all ear patients have more or less tinnitus. In the writer's experience a greater or less degree of it is so common in chronic deafness that its absence in any case is worthy of comment. It is seen in diseases of all parts of the ear. It is often a prominent symptom in cases of impacted cerumen, also in furunculosis of the meatus externus. It may also be found in cases of tubal catarrh, of stricture of the Eustachian tube, of acute otitis media, catarrhal or purulent; it is a common symptom in all forms of chronic otitis media, and in the lighter forms of otitis interna, where the auditory nerve is not completely destroyed. The worst and most obstinate cases are those of otosclerosis. This disease, which has been only of late differentiated from chronic aural catarrh, is one of the most frequent causes of tinnitus, which is usually an early, and may be during months or years the only, symptom.

Tinnitus presents itself under various forms, both as to quantity and as to quality of noise, and also as to constancy or intermittency of its occurrence. As to quantity, the noise may vary from a soft, barely noticeable rustle, as of the leaves on a tree, to an excessively loud screaming sound, like a steam whistle. The latter extreme is, of course, rare. All intermediate degrees, however, are constantly seen. The quality of the sound varies greatly. It may be high-pitched or low-pitched, blowing like the wind, whistling like the escape of steam, crackling like a wood fire, or occasionally detonating like an exploding firecracker. More serious are those rare cases in which the noise takes the form of music, or of human speech. It is always possible that in such a case we are dealing with a psychopathic patient, and we must therefore be on the watch for the development of genuine auditory hallucinations. Many patients have two or more kinds of tinnitus at once. The writer has at present two such cases under observation.

Panse (*Zeit. für Ohrenheilkunde*, 1898, p. 244) attempted to show that low-pitched sounds occur chiefly in diseases of the sound-conducting apparatus, and those of high pitch in conditions affecting the labyrinth. His conclusions are denied by Politzer, with whom the writer is inclined to agree, never having been able to satisfy himself that there was any necessary relation between the kind of noise and the anatomical condition causing it.

Constancy or intermittence of the noise is a more important feature, because it seems to have a bearing upon prognosis. In certain cases tinnitus occurs in waves, synchronous with the beat of the pulse. In these cases it is always possible that the underlying lesion is of the type of a simple congestion, which may be curable, partly or wholly. In other cases the wave of sound comes with inspiration or expiration (respiratory tinnitus). These cases are sometimes due to the rushing of the inspired air through an abnormally patulous Eustachian tube, as in a case reported by Kerrison (*Med. Record*, April 19th, 1902). In this particular case treatment was wholly successful, and the patient, a man over seventy years of age, was completely cured.

Some patients say that they hear the noise only when lying down, and especially at night. These are usually cases of the milder type. This may depend upon the recumbent position, or more probably perhaps upon the fact that during the hours of rest one has fewer distractions than at other times. To interfere seriously with sleep, tinnitus must be very severe. There are other cases in which the tinnitus is made worse by bending forward, or by or during heavy exercise.

It must also be noted that some persons have the knack of causing at will certain sounds in the ear. These are usually clicking sounds, probably caused by opening and shutting the pharyngeal orifice of the Eustachian tube, by action of the tensor palati muscle. This action sometimes takes place involuntarily, and the noise thus produced is one of the class known as *entotic*. These noises are actual, as opposed to those which are strictly subjective, and in many cases may be heard by the examiner. Apart from the clicking caused by action of the tensor palati, there may be clonic contractions of the intrinsic muscles of the ear (tensor tympani and stapedius) which cause ticking or humming sounds. There are also the so-called vascular entotic noises, caused by anomalies of the blood-vessels. According to Politzer ("Diseases of the Ear," 1902, p. 777) they may be due to the following pathological conditions: dilatation of the arterial branches within the tympanum, changes in the carotid canal, cardiovalvular lesions, goitre, cranial aneurisms, or chlorosis (*bruit du diable*). They are synchronous with the pulse, and may, in some instances, be heard by auscultation all over the head. Attempts which have been made to relieve these cases by ligating the carotid artery have given unsatisfactory results. In a case operated upon in this manner by Linsmayer, and reported by Politzer (*loc. cit.*), the operation was followed by death from softening of the corresponding cerebral hemisphere.

Prognosis.—It goes without saying that the prognosis as to recovery in any given case depends upon the nature of the underlying anatomical cause. In a general way, however, it may be said that the hope of recovery from tinnitus is much less than the hope of relief from deafness. Many patients who complain of both deafness and tinnitus gain a very fair degree of hearing, while their annoying ear noise continues about the same. Cases of intermittent tinnitus offer a somewhat better prognosis than where the noise is constant, as the causative lesion is apt to be of a less permanent character. Slighter degrees of tinnitus, and those in which the noise has existed only for a short time, are more favorable than those of severer character and longer standing.

Treatment.—The successful treatment of tinnitus depends entirely upon the possibility of discovering and removing its cause. Therefore it may be said that the treatment of tinnitus is the treatment of diseases of the ear. Accuracy in diagnosis is essential. Every patient is entitled to the most careful and painstaking examination of which the aurist is capable. A complete history of the case must first be taken, and all possible causes, apart from the ear, must be considered. Next comes a detailed physical examination of the auricle, the external meatus, the drum membrane, and the mastoid region, followed by examination of the nose and throat. By means of the auscultation tube we should listen to the sounds that are generated while air is being forced through the Eustachian tube into the middle ear. Finally, all known means of functional testing of the hearing should be employed—voice, watch, acoumeter, the various tuning-fork tests (Rinné, Weber, Gellé); also the Galton-whistle test for the upper tone limit should be tried in order to acquire as complete a knowledge as is possible of the anatomical condition. Treatment then is directed to rectifying what is wrong, so far as this can be done. Impacted cerumen must be removed. Furunculosis or other disease of the canal calls for appropriate treatment. A retracted drum membrane or a chain of ankylosed ossicles must be restored to the normal condition by inflation, pneumo-massage, or the Lucae pressure probe. A contracted Eustachian tube calls for dilatation by the use of bougies. The ordinary filiform urethral bougie serves this purpose well. Of intratympanic conditions suppurative cases call for measures which tend to dry up the discharge, thorough cleansing, the removal of granulations, polyps, or cholesteatomatous masses, and perhaps for ossiculectomy or the Schwartze-Stacke operation (see Vol. VI., p. 706).

Of the non-suppurative cases it is very important to differentiate between chronic aural catarrh and otosclerosis. The former disease is best treated by attention to the nose and throat, with such local treatment for the middle ear as has been mentioned above. The latter disease has only lately been recognized, and, as it is a frequent cause of obstinate tinnitus, calls for special mention. It is of the nature of an hyperostosis, and usually affects the region about the oval window, on either the tympanic or the vestibular side, so that it may give symptoms of ankylosis of the stapes, or of labyrinthine involvement, or both. It is a chronic progressive disease with intermissions. During the active periods there is usually a reddish tinge to the drum membrane, due to the shining through of the congested promontory. At other times the membrane may appear normal, in both character and position. The disease is due to injury, or to extra-aural causes, usually auto-intoxications, from gout and allied conditions, or to disease elsewhere in the body, acting reflexly from a distance, as certain uterine and ovarian conditions. Hartz (*Ann. Otol., Rhinol., and Laryngol.*, vol. xi., p. 637) says the disease is very frequent at the puerperium. The treatment is to be directed to the cause. In the acute stage active local treatment aggravates the condition. Probably in the future, when the physiology of nutrition shall be better understood, some dietetic and hygienic régime will be discovered which will help these patients. At present no treatment does much good.

Tinnitus, due to labyrinthine disease, is often syphilitic. Such cases call for iodides in large doses, and show better results with mercurial inunctions than without them. Pilocarpine also sometimes helps these cases. It is best given at bedtime, beginning with one-tenth of a grain and increasing until the dose is sufficient to cause profuse sweating.

Palliative local and general treatment usually gives only temporary relief. Politzer ("Diseases of the Ear," 1902, p. 778) recommends sodium bromide internally, five to fifteen grains three times a day. He also recommends a small blister over the mastoid region, followed by applications to the vesicated area of antimonial ointment or bisulphate of quinine. He also speaks of instillations into the meatus of about five drops of a mixture of tincture of valerian, 4 parts, and acetic ether, 3 parts, in glycerin, 40 parts. These measures at least tend to satisfy the patient that his distressing malady is not being neglected by his physician. *Donald M. Barstow.*

TIN, POISONING BY.—Metallic tin, if pure, has no injurious action on the system. The soluble salts of tin, especially the chlorides, are violent irritants; but cases of poisoning by them have rarely come under observation. Two grams (ʒ ss.) of a solution of the chloride has caused death in three days. In the treatment of cases of poisoning by these compounds, milk or albumen, alkaline carbonates, and emetics are indicated first. The after-treatment should be symptomatic.

The compounds of tin owe their toxicological importance chiefly to the fact of their frequent occurrence in various articles of food; but whether this occurrence of tin is attended with any danger to health is still a disputed question. A non-fatal case of acute poisoning has been attributed to the use of salt which had been dried on a tin dish on the stove. It has been suggested, however, that the symptoms described might more reasonably be attributed, in the absence of a chemical analysis, to lead poisoning; since much of the tin plate formerly used was not pure tin, but an alloy of tin with lead.

Many cases of acute poisoning have followed the use of canned foods, and in some of these cases the symptoms have been attributed to tin; but rarely, if ever, has the theory of tin poisoning been substantiated by an analysis of the suspected food. It is a well-recognized fact that many cases of acute sickness have been caused by the ingestion of food which was entirely free from injurious metals. It is considered, therefore, more reasonable, by some authorities, in the absence of any chemical analysis, to attribute the symptoms which frequently follow the ingestion of canned foods to some cause other than metallic poisoning, such as putrefactive changes taking place in the food; or, in a certain number of cases, to idiosyncrasy. Some, while denying the probability of tin poisoning, admit the possibility of poisoning by other metals, as lead or zinc, the former derived from the tin plate or from the solder, the latter from the soldering fluids used in sealing the cans.

It is not disputed that canned foods frequently contain tin, which has been dissolved from the tin plate by the action of acids or other constituents of the food, or which has been introduced by the careless use of stannous chloride, which is a constituent of some of the soldering fluids used in sealing the cans. But the quantity of tin is usually small, varying from a few one-hundredths of a grain to one grain per pound, rarely approaching, however, the higher figure. These amounts are not likely to give rise to symptoms of acute poisoning. Winter Blyth states that he found in some samples of canned fruits as much as 14.3 grains of stannous hydrate per pound, and that the average amount in all examined was 5.2 grains per pound. In some cases the juice had a metallic taste. With such quantities of tin, in a form easily absorbed by the system, the possibility of acute poisoning must be admitted. But the facts at present known to us do not seem to warrant the conclusion that acute tin poisoning, as a result of the use of canned foods, is an occurrence to be greatly feared. A quantity of tin salt sufficient to cause poisoning would probably be recognized by the taste, and the food thus contaminated be rejected as unpalatable.

Stannous chloride is sometimes added to the cheaper grades of molasses to lighten the color and give the sample the appearance of a higher grade of molasses; and sugar crystals are said to be washed with a similar solution, the greater part of which afterward passes into the molasses. Whether this use of the tin salt is attended with any danger to the consumer has not been determined. The chloride is immediately decomposed by some of the constituents of the molasses and converted into an insoluble compound, which is deposited with the sugar, the clear molasses usually not retaining any of the tin. The composition and physiological action of the resulting insoluble compounds have not been investigated.

The question of chronic poisoning, as a result of the habitual or frequent use of foods containing traces of tin compounds, is an important one, which has not yet been thoroughly investigated, and concerning which opinions differ.

In order to determine how far absorption into the circulation may produce disturbances of health, T. P. White has investigated the action of the double tartrate of tin and sodium, and of stanno-triethyl acetate on animals. He places tin near lead in its toxic power. The administration of the acetate is followed by two series of symptoms—one referable to the digestive tract, namely, loss of appetite, nausea, vomiting, abdominal pains, and diarrhœa; the second referable to the central nervous system, manifested by weakness of the extremities and paralysis, diminution of the power of the heart, severe respiratory disturbances, and convulsions. The urine is scanty, has a high specific gravity, and frequently contains albumin. According to White, tin acts directly on the intestinal tract, whatever the channel by which it is introduced. Post-mortem examination showed: Mucous membrane of the stomach and intestines soft, covered with mucus, and hyperæmic; heart in diastole; blood thin and dark; lungs collapsed and hyperæmic; liver pale and somewhat enlarged.

Similar results were obtained with the double tartrate, but larger doses were required. After the administration of these salts tin was found in the muscles, liver, kidneys, brain, heart, and urine. The blood in most cases contained no tin. White concludes, however, as a result of many experiments, that there is no danger of tin poisoning resulting from the contact of fruits and vegetables with the metal, and that cases of poisoning which have been attributed to tin were due to solder or to metallic impurities in the tin.

Ungar and Bodländer have also investigated the action of the two tin salts studied by White, and with similar results; concluding that the question of the poisonous action of the tin compounds, aside from any local effects, must be answered in the affirmative. To determine whether foods containing tin are likely to produce any local or general effects, they fed dogs and rabbits on fruits, etc., containing small quantities of tin, but failed to observe any irritant action on the mucous membrane of the stomach and intestines. The absorption of tin under such conditions was proven by its detection in the liver, spleen, kidneys, brain, heart, muscles, and urine. None was detected in the blood. The authors also detected tin in the urine of man in two cases.

William B. Hills.

TOBACCO (*Tabacum*, U. S. P.; *Tabaci Folia*, B. P.; *Folia Nicotianæ*, P. G.; *Nicotiane, Tabac*, Fr. Cod.) consists of the dried leaves of *Nicotiana Tabacum* Linn., of the order *Solanaceæ*. It is a rank, viscidly hairy plant, four to six feet high, with coarse, entire, alternate leaves, having a disagreeable odor and taste and turning brown on drying. The simple stems terminate in panicles of rose-purple flowers. The calyx and corolla are five-toothed, the former tubular, the latter funnel-shaped and conspicuous, about two inches long. There are five stamens and a single two-celled ovary. The fruit is a two celled capsule an inch long, opening by two or four valves. The seeds are small and numerous.

Tobacco is a native of America, but is now grown in many parts of the world. The seeds are sown in beds and in early spring are transplanted. The flowering tops are cut off to encourage the growth of the leaves. In August or September the leaves are gathered, dried under cover, then piled up and allowed to ferment or "sweat." The details differ in different tobacco-raising regions, and the further process depends upon the kind of tobacco to be made.

Nicotiana Persica and *Nicotiana rustica* are also used in making Turkish tobacco, from which Egyptian and Turkish cigarettes are made.

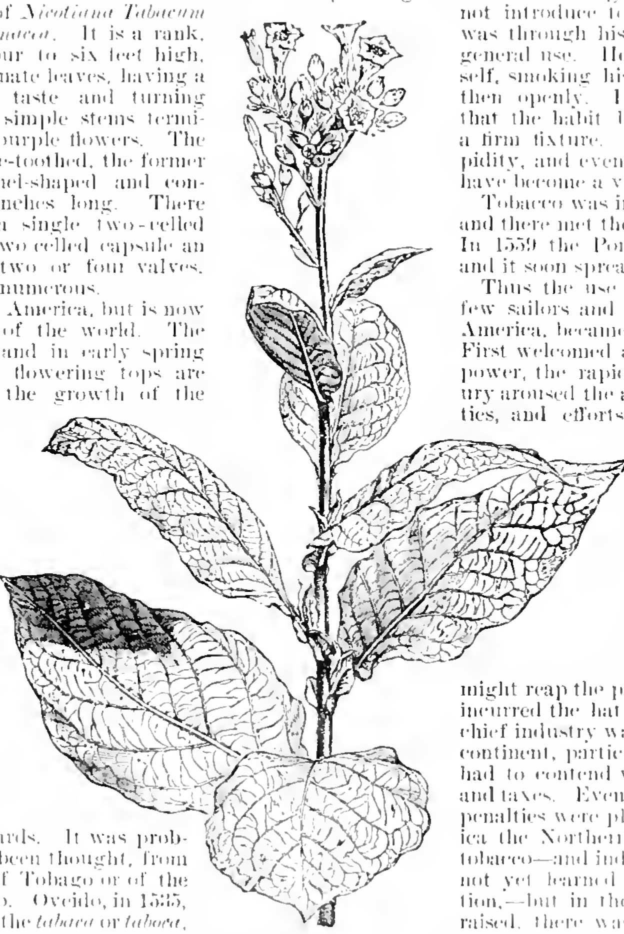

Fig. 4625.—Nicotiana Tabacum Linn. (Baillon.)

The word *tobacco* was introduced by the Spaniards. It was probably not derived, as has been thought, from the name of the island of Tobago or of the Mexican state of Tobasco. Oveido, in 1535, described an instrument, the *tabaca* or *taboca*, used for smoking or inhaling various substances. It was a hollow stick, shaped like the letter **Y**. The small ends were placed in the nostrils and the powdered drug was put in the other end. Ernst believes that the term was derived from a Guarani word meaning "to eat, sucking." Las Casas applied it to rolls of tobacco like cigars. The words *uppowoc* and *pætun* were used in Europe at first, but *tobacco* soon displaced them.

Tobacco was introduced into Europe from the American Indians. Smoking was first observed during the first voyage of Columbus. In November, 1492, he sent an expedition into the interior of Cuba, and members of the party noticed the Indians smoking rolls of the dried leaves, the prototypes (shall we say?) of our Havana cigars. Cartier and other followers of Columbus also observed the practice, and the sailors returning from these early expeditions carried it back to Europe.

The introduction of the habit into other European countries and its spread through the whole world is a most remarkable chapter, and one which can only be touched upon here. In 1559 Jean Nicot, ambassador from France to Lisbon, whose name is perpetuated in that of the genus Nicotiana, sent some seeds to Catherine de Medici, who powdered them and used them as medicine. Thus tobacco was introduced into France.

In England tobacco was known as early as 1564, when Hawkins described its use in Florida. The habit was not introduced till 1586, when Sir Walter Raleigh's unsuccessful Virginian colony, under Ralph Lane as governor, returned to England in the vessels of Francis Drake. Many of the colonists had learned to smoke from the Indians and they brought the habit home with them. Raleigh himself, not being a member of the party, did not introduce tobacco into England, but it was through his influence that it came into general use. He was a famous smoker himself, smoking his pipe at first secretly and then openly. His social position was such that the habit became first a fad and then a firm fixture. It spread with amazing rapidity, and even Queen Elizabeth is said to have become a victim.

Tobacco was introduced into Italy in 1589, and there met the same enthusiastic approval. In 1559 the Portuguese carried it to India, and it soon spread all over the East.

Thus the use of tobacco, starting with a few sailors and adventurers returning from America, became general all over the world. First welcomed as a drug of rare medicinal power, the rapid spread of its use as a luxury aroused the apprehensions of the authorities, and efforts were everywhere made to stamp it out. In England James I. wrote his "Counterblast to Tobacco" in 1603, and followed it with many restrictive laws, as ineffectual as they were severe. Both James I. and Charles I. imposed the severest restrictions and taxes on tobacco, ostensibly to control its use, but really to so regulate the trade that they might reap the profits therefrom. Thus they incurred the hatred of the Virginians, whose chief industry was tobacco-growing. On the continent, particularly in Italy, the smokers had to contend with papal bulls, civil laws, and taxes. Even in Persia and Turkey severe penalties were placed on smokers. In America the Northern colonies legislated against tobacco—and indeed some of our States have not yet learned the futility of such legislation,—but in the South, where tobacco was raised, there was naturally no such opposition. The extent to which tobacco is used to-day may be judged from the fact that in England in the years 1899 and 1900 the consumption amounted to about two pounds per head of the population.

Tobacco needs no description. Its only important active principle is nicotine, which is present to the extent of from one to eight per cent., in combination with citric and malic acids. It is a volatile, oily fluid, soluble in water, and, when fresh, nearly odorless and tasteless. On standing it turns brown and develops the familiar odor of tobacco. The exact structure of the nicotine molecule ($C_{10}H_{14}N_2$) is not yet known with certainty. It surely contains two organic groups, one of which is pyridine. The other has been thought to be piperidine and, more recently, a hydrated pyrrhol ring. Moore and Row believe that the molecule contains a reduced pyridine ring. Besides nicotine dried tobacco contains pyridine and other decomposition products and an oil which is of importance in determining the flavor.

As a medicine tobacco is obsolete. Among its former uses were the reduction of strangulated hernia and intestinal obstruction by tobacco enemata; the resuscitation of the apparently drowned by blowing smoke from a reversed pipe into the rectum; the relief of baldness and other skin diseases by its external application. Lumbermen and other ignorant persons sometimes treat wounds by the disgusting use of tobacco sputum. Though still retaining its place in the Pharmacopœia, it is too dangerous to be of practical value. Its importance depends wholly upon the prevalence of its use as a luxury.

Physiological Actions.—Nicotine is classed by Schmiedeberg with pilocarpine. Its most notable effects are increased glandular activity (salivation, sweating, and lachrymation), contraction of the non-striated muscles of the alimentary tract (vomiting and catharsis), of the bladder (micturition), of the iris (myosis), and of the arteries (increase of blood pressure). These effects are due to stimulation of the sympathetic nerve ganglia. They are for the most part but temporary, stimulation giving way to paralysis. They are just the reverse of those due to atropine. But the latter acts on nerve terminations in glands or muscle cells, so that, while the effects of nicotine are prevented by the previous administration of atropine, those of atropine are uninfluenced by nicotine.

Moderate doses of nicotine cause slowing of the pulse followed by a return to normal or to a rate slightly above normal. Large doses cause no slowing at all. It must be remembered that the heart is slowed by depressor or inhibitory influences coming through the vagus and accelerated through the sympathetic. Both sets of nerve impulses must pass through ganglia before reaching the heart muscle. Nicotine at first stimulates the ganglia on the vagus, thus causing slowing of the heart, while it afterward paralyzes them and so produces the opposite effect. The action is further complicated by the fact that the accelerator ganglia are probably also affected, and still further by a direct action on the cardiac muscle fibres or the nerve terminations in them, for, after removal of the ganglia, nicotine first slows and then quickens the heart.

The blood pressure is markedly though temporarily increased by nicotine, owing to stimulation of the vasoconstrictor ganglion cells. The pressure may rise to two and a half times the normal. The subsequent fall is due to paralysis of the same ganglia. Brunton and Tunnicliffe show that pyridine causes a fall, and Moore and Row therefore attribute the rise to the reduced portion of the nicotine molecule. This effect on the blood pressure is important. Obviously its frequent repetition might produce the most widespread results—results having to do not only with the vessels themselves, but also with all the organs whose supply of blood is affected. Accordingly Huchard and others attribute to this action many of the evils resulting from the abuse of tobacco.

As to the effects on the coronary circulation, though of great clinical importance, little is known. Beyer perfused nicotinized blood through the excised mammalian heart and found a short period of increase followed by a decided and permanent decrease of the volume of the coronary circulation. This appeared to be independent of any change in the action of the heart itself. His results, however, are not altogether conclusive, and it would be unsafe to infer that in man the use of tobacco causes such changes.

The respirations are first quickened and deepened, and hence there is the appearance of dyspnœa. Larger doses cause decreased respiratory activity and the breathing becomes progressively slower and shallower. In lethal doses it is the arrest of respiration that causes death. These results are due to stimulation of the respiratory centre in the medulla, followed by paralysis of this centre.

The stimulation and subsequent paralysis of glandular secretions by nicotine has been especially studied in the salivaries. As the nicotine acts only on the ganglion cells, when secretion has been stopped by it activity may again be brought about by the injection of muscarin or pilocarpine as these act on the nerve endings, or by mechanically stimulating the nerves between the ganglia and the gland. The same facts have been established in regard to sweating by Langley. There is no evidence that the secretion of urine is increased by nicotine, though micturition results from contraction of the bladder wall.

The contraction of the involuntary muscles of the alimentary canal is probably due to stimulation of the sympathetic ganglia in the walls of the organs. The result is the vomiting and purging, so prominent in cases of acute poisoning, and perhaps the mild catharsis which is one of the ways in which an old smoker is prone to excuse his habit.

The action on the central nervous system is first one of stimulation, as shown by the increased respiratory activity and heightened reflexes and in larger doses by convulsions. The spinal cord, and particularly the lower brain centres, are chiefly involved. The stimulation is followed by marked depression of the whole central nervous system, so that when the animal does not die in the convulsions, there are slow, shallow breathing, lost reflexes, and unconsciousness.

The actions of nicotine are rapid in onset and of brief duration. They are not cumulative. It is a matter of common observation, as well as one capable of experimental demonstration, that tolerance is easily established. In some this appears to be almost absolute, while others cannot "learn to smoke" at all.

Acute Tobacco Poisoning.—Mild cases of poisoning by tobacco are common among smokers who have not yet thoroughly established a tolerance, and they have occurred in others from breathing air containing the smoke. Yet in spite of the extensive use of tobacco and its extremely poisonous nature, serious cases of acute poisoning are extremely rare. Death has resulted from the internal use of infusions and decoctions, from enemata, and even from external application. Tobacco is used by ignorant persons as a household remedy and thus serious poisoning has resulted from the administration of water saturated with smoke to children. Chewers have been poisoned by swallowing tobacco juice and children from sucking old pipes. Taylor describes the case of a child of three who died as a result of blowing soap bubbles with its father's disused pipe.

The use of nicotine for suicidal purposes is rare. A few homicides are recorded, of which the most famous are those of the poet Santeul and of the Count Bocarmé. The former was killed by drinking wine with which snuff had been mixed. In the other case Bocarmé killed his brother-in-law by forcibly giving him nicotine, which he had himself prepared after several months' study of the process.

The symptoms of mild poisoning, such as occur in inexperienced smokers, are nausea, vertigo, vomiting, tremor, salivation, clammy sweating, and prostration. Severer symptoms rarely result from smoking as the terrible nausea deters the smoker from carrying his indulgence to the danger point. Where nicotine or tobacco is introduced in greater quantities there is violent purging, often with abdominal pain and involuntary micturition. Clonic convulsions are always seen in severe cases provided the person affected lives long enough.

They are followed in fatal cases by mental confusion, unconsciousness, and death from respiratory failure. The pupils are generally contracted, or at a later stage dilated. The pulse is small and weak. Where still larger doses are taken, convulsions may begin almost immediately and end in death from arrest of respiration. Enormous doses of nicotine kill almost instantaneously. The Bocarmé case was fatal in about five minutes. In other cases death may be delayed for several hours or several days.

The lethal dose of nicotine is not known. According to Witthaus it is probable that two or three drops of pure nicotine might prove fatal. An infusion of thirty grains of dried tobacco leaves has caused death.

For treatment the unabsorbed drug should be removed from the stomach or rectum with the tube. Tannin is recommended as a chemical antidote to render the nicotine insoluble, and atropine in full doses to counteract its physiological actions. Stimulants and heaters should be freely used. As death results from respiratory failure, this should be met by artificial respiration.

Chronic Tobacco Poisoning.—Tobacco is used as a luxury by chewing, snuffing, dipping, and smoking. In chewing the poisonous substances come into close contact with the mucous membrane, but will produce little local effect beyond the mouth. Salivation is marked, since to the action of the absorbed nicotine on the glands is added the reflex action due to irritation of the buccal mucous membranes. Snuff takers suffer particularly from local irritation of the upper respiratory passages. The effects of snuff have in certain cases been modified by the presence of lead. "Dipping" is a habit, formerly seen in the South, of taking snuff by dipping into the powder a stick, which is then rubbed on the teeth or gums.

Smoking is the commonest method of using tobacco. Its effect on the upper respiratory passages is especially marked, and is due to heat as well as to the presence of chemical irritants. The nicotine and other active principles are more or less modified by partial combustion. The composition of tobacco smoke was studied in 1872 by Vohl and Eulenberg, who claimed that it contained no nicotine. They demonstrated a long list of substances, including a series of pyridine and picoline bases, to which they ascribed the effects usually attributed to nicotine. Since then the subject has been repeatedly investigated, chemically and physiologically, and the nicotine in the smoke has been estimated at amounts varying from nothing to fifty per cent. of that in the tobacco. Heubel, Vas, and others have proven that nicotine is present, the latter finding no other poisonous substance. For practical purposes it would appear to be of little moment whether the effects of smoke are due to nicotine or to decomposition products having essentially the same actions.

Tobacco is smoked in pipes, cigars, and cigarettes. The first mentioned method is probably the most deleterious because very strong tobacco is thus used. The black, oily juice, which collects in the stems of foul pipes, and which has been shown by Heubel to be extremely poisonous, is partly taken in when the pipe is again smoked. In cigars, on the other hand, the nicotine, which is partly evaporated and partly broken up in the burning end, is to some extent recondensed and deposited in the region near the mouth. It is then thrown away with the stub. In spite of the strong lay opinion to the contrary, it is altogether probable that, used in moderation, cigarettes are the least harmful method of smoking, though they have some dangers peculiarly their own. They are so mild that the smoker is tempted to use a large number of them and thus he constantly, though slowly, absorbs a great amount of poison. The same mildness leads to their use by minors and women, and causes the smoke to be inhaled. It is said to be especially dangerous for a pipe-smoker to use cigarettes, as he thus learns to inhale the smoke, a practice which is objectionable with the pipe. The belief that cigarette tobacco contains opium, or that the paper contains deleterious substances, has little or no foundation. Neither has the especial prejudice against Turkish and Egyptian cigarettes.

Operatives in tobacco factories are sometimes affected by the fine particles of tobacco dust in the air. In a case of the writer's, a girl of fifteen, predisposed by bad habits, late hours, and the excessive use of tea, worked for a week as "stripper" in a small room full of tobacco dust. She vomited on the first two days and fainted four times in the week. When seen, she complained of throbbing sensations in the head, violent cardiac pain, dyspnœa, and palpitations, and presented a rapid and irregular heart and marked anæmia. Such symptoms are not uncommon in beginners, but tolerance is soon acquired, permitting them to work with impunity in the dust. Dowling, studying chiefly the ocular symptoms, found that forty-five out of a hundred and fifty men working in the tobacco factories of Cincinnati showed evidences of chronic tobacco poisoning. But all of these men smoked or chewed. Apart from anæmia—a common symptom among girls working in factories of any sort—there was little evidence of harmful results in women or men who did not use tobacco. Workers sometimes show conjunctivitis and irritation of the upper respiratory passages; but these effects are rare, and it does not appear that the manufacture of tobacco is especially dangerous.

Before considering the effects of the continuous use of tobacco on the various organs, it should be said that harmful results are, considering its almost universal use, rare. In most cases tobacco is not the only source of the trouble, morphine, tea, coffee, alcohol, or other injurious habits being present.

The effects of tobacco on the mouth, throat, and upper respiratory passages are due to local irritation rather than to the action of nicotine after absorption. They are more marked from smoking than from chewing. And every pipe smoker knows that mild tobacco "bites the tongue" more than strong. These facts suggest that the irritation is due rather to products of combustion than to nicotine. Catarrhal inflammation of the nasopharynx with marked hypersensitiveness of the throat is common in smokers. It may extend through the Eustachian tubes to the middle ear. It is possible that the ear may be injured in another way, viz., by the production of a neuritis of the auditory nerve similar to that seen in the eye, an action of course taking place after absorption. However, this rarely, if ever, results. Excessive chewers sometimes show inflammatory conditions of the mouth and throat and extreme discoloration of the teeth, which are sometimes worn down to a level with the gums. Snuff-takers suffer from various inflammatory conditions of the nose. Inspissated masses of snuff have formed nasal calculi. It has been said that smoking predisposes to cancer of the lip. If there is any truth in this the disease is due to local irritation.

The effects of tobacco on the alimentary system have been a subject for experimental study as well as for clinical observation. They are partly due to the swallowing of sputum containing toxic substances from the smoke or bits of tobacco from cigars held long in the mouth and chewed. The stomach may also be injured indirectly through the circulatory system. The symptoms are those of chronic gastric indigestion, hyperacidity, or flatulence. These symptoms are so common and so many excessive smokers are also excessive drinkers that the importance of tobacco as a factor is difficult to estimate. In rabbits fed for months on cabbage soaked in tobacco infusion, Adler found no gastric symptoms after the first few days, and the appetite continued unimpaired. On the other hand, it has been noticed by military writers (Korloff) that where food is lacking tobacco markedly decreases the sensation of hunger.

In Adler's experiments the liver became enlarged, and on microscopic examination showed marked proliferation of the interlobular connective tissue with new formation of bile ducts, but without any involvement of the hepatic cells. These experiments were incomplete and not altogether conclusive. Adler does not draw any comparison between the processes observed and human cirrhosis, and indeed tobacco has never been noted as one of the causes of the latter. As a result of somewhat similar experiments Kohos found small, hard livers.

The effects on the blood have been studied experimentally by Vas on puppies. After eight weeks he noted marked anæmia, the hæmoglobin and red corpuscles decreasing over a half. The solid residue and the alkalinity decreased a little while the white corpuscles were decidedly augmented.

Of all the effects of chronic tobacco poisoning the most important, both from their frequency and from their severity, are those which have to do with the circulatory system. Though sometimes seen in boys, they generally result from long-continued abuse. They are said to be most frequently caused by Havana cigars. Many if not most of the cases, like the writer's patient previously referred to, are predisposed by other conditions, such as alcoholic excess, emotional strain, over-exercise, nervous disease, convalescence from acute diseases, bad habits, or indigestion. Epidemics of tobacco angina, like those described by Kleefeldt and Gélineau, may depend largely on such predisposing influences. In the latter instance a series of cases appeared on a French man-of-war, where the men, debilitated by scurvy and poor food, smoked to excess in a small close apartment.

Although the clinically observed effects of tobacco have not been fully explained, the following facts are of importance: 1. The work of the heart is increased by the vaso-motor contraction and consequent increase of the peripheral resistance, *i.e.*, the blood pressure. That this results from the administration of nicotine has been amply demonstrated by experiments. But, so far as the writer is aware, it has not been shown to result in habitual smokers from each indulgence. Such proof is all the more needed since smoke contains pyridine as well as nicotine, and the effect of the former is to reduce, and not to raise, the blood pressure. 2. Any such additional work has to be done by a heart hampered by the disturbing action of the drug on the nerve centres and muscle fibres. 3 The heart is at the same time further embarrassed by decrease of its blood supply through contraction of the coronaries. That this takes place has not been conclusively demonstrated by experiments, though the work of Beyer points in this direction, but it is accepted clinically by Huchard, Farvarger, and others.

It is probable that in far the greater number of cases the cardiac symptoms of chronic nicotine poisoning are due to functional disturbances without gross pathological lesions. Occasionally, however, after long continued abuse, hypertrophy may result from the above-mentioned factors, especially the first. Fatty degeneration and other forms of myocarditis have been attributed to the myocardial ischæmia Huchard believes that the constantly repeated vascular contractions and rises of blood pressure may result in arteriosclerosis. Tobacco is not ordinarily considered to be one of the causes of this common condition. There is, however, just a suggestion in some recent experimental work that such may be the case. If, as Huchard believes, the sclerosis may involve the coronaries, myocarditis and true angina might result as from the same conditions due to any other cause.

The symptoms most commonly seen are those of "irritable heart." They are often associated with digestive disturbances Palpitations are commonly complained of, with dyspnœa, ordinarily mild. Asthmatic symptoms may be present Heart pain is common; it is usually slight and transient, but every gradation exists from the mildest to the terribly severe attacks justly described as anginal. Pallor, cold extremities, cold sweating, tremor and muscular weakness, small and feeble pulse, vertigo, headache, amnesia, psychical irritation, and even aphasia or transitory hemiplegia (spinal or cerebral anæmia) are considered by Huchard to result from the contraction of the vessels of the organs involved. To say the least, many of these symptoms are extremely uncommon.

Physical examination of the heart may show absolutely nothing abnormal. Generally there is irregularity or intermittence, which may be very marked. Rapidity is common, and is especially shown in the undue degree and permanence of the increase in pulse rate on suddenly sitting up or after slight exertion. The symptoms and signs of hypertrophy, fatty degeneration, and arteriosclerosis need not be described here, since they are at best rare and doubtful results of tobacco, and do not differ from the same conditions produced in other ways.

Attacks of heart pain, severe enough to be classed as true angina pectoris, are extremely rare. Osler states (1897) that he has seen but two cases as results of tobacco. Huchard describes three forms: (1) Functional (*angine spasmo-tabagique*), due to spasm of the coronaries. (2) Organic cases (*angine scléro-tabagique*), due to organic stenosis of the coronaries. (3) A benign form (*angine gastro-tabagique*), precipitated by gastric disorder. The first of these, though the symptoms may be very severe, almost always recovers in a fortnight after the withdrawal of tobacco; the second is always fatal; the third is the most benign of all, and disappears on withdrawal of the tobacco or curing the indigestion.

The following are among the peculiarities of the angina due to tobacco mentioned by Huchard: Vaso-motor symptoms are common—pallor, vertigo, small pulse, syncope. Other evidences of nicotine poisoning, like amblyopia, may be seen. Irregularity and rapidity of the pulse are more common than in angina due to other causes. The attacks are more apt to be slight or abortive, and are usually spontaneous.

Various effects on the central nervous system have been ascribed to tobacco. Vertigo, headache, muscular tremor, and debility are not uncommon. Tobacco as a rule favors sleep, but an unusually strong cigar may have the opposite effect. Huchard attributes all these things to ischæmia of the nerve centres, as he does the rare cases of aphasia and transient hemiplegia. In the experiments of Vas, already alluded to, degenerative changes were noted in the cells of the spinal and sympathetic ganglia similar to those caused by certain other poisons. Peripheral neuritis and neuralgia are described, but it is probable that serious nervous diseases of an organic nature, such as locomotor ataxia or general paralysis, are never caused. Insanity has been attributed to tobacco and a peculiar psychosis is mentioned. Its rarity may be judged by the fact that Kraepelin says he has never seen anything of the kind. Any influence that tobacco has in this respect is probably an indirect one, due to the general physical depression, or to the marked injury of some particular organ.

The effect of tobacco on the eyes is universally recognized. An amblyopia of a specific type may certainly result from the abuse of tobacco, though alcohol is often an auxiliary factor. It is commonest in men beyond the age of thirty-five, and is said to be more common in smokers than in chewers. Dowling found some evidence of amblyopia in 45 out of 150 tobacco workers, all of whom smoked or chewed. Hirschberg found 7 cases in an ophthalmic clinic of 18,000; Galezowski, from 5 to 15 in 1,000; Landolt, 12 in 2,771. Pathologically the amblyopia is considered by some to be a retrobulbar interstitial neuritis, involving the papillo-macular bundle. Recently several investigators have attributed the cause to retinal changes taking place in the macular region, the degenerative changes in the papillo-macular bundle being secondary.

There is dimness of vision, not improved by glasses. The patient may see best at night or in a dim light. The most characteristic finding is the central scotoma for color, a condition which is almost pathognomonic of toxic amblyopia. The ability to distinguish green is usually lost first, then red, and finally blue. The scotoma may later exist for form as well as for color. The periphery of the visual field remains normal. With the ophthalmoscope the papilla is normal at first or slightly congested, then evidences of atrophy appear on the temporal side of the disc and finally become general.

Certain French writers have claimed that tobacco may cause sexual impotence, and have found experimental evidence of degenerative processes in the testicles. Symptoms of this sort are certainly not common, and again there is difficulty in establishing the fact that tobacco is the cause.

As to the effects of tobacco on the general development, the puppies to whom Vas continuously administered nicotine lost weight very decidedly, while the rabbits, to whom Adler administered tobacco, retained perfect health for months. The statistics for one of the Yale classes is said to have shown that the men who did not use tobacco gained much more rapidly in weight, height, chest girth, and lung capacity than the moderate smokers, while the latter exceeded the excessive smokers. Thus the popular belief that tobacco "stunts the growth" appears to have some support.

In some diseased conditions the use of tobacco is undoubtedly injurious, though here, if a patient has always used tobacco, the hardship entailed by giving it up may be more deleterious than its continuance in moderation. In mental diseases Bucelli considers that its use is inadvisable, particularly in convalescents. As regards tuberculosis the views of different writers have varied from those of Melier and Ruef, who considered that tobacco was beneficial, to that of Benjamin Waterhouse, who, in 1805, thought that tobacco was the cause of the prevailing ill health of Harvard students, and especially of the increase in phthisis. Recently Stern has shown that the use of tobacco may aggravate an existing glycosuria, and even, though infrequently, cause it.

Tazzinari has subjected various pathogenic organisms to the action of cigar smoke, and shown that it very decidedly retards the development of some pathogenic bacteria, and wholly prevents that of certain others. The effect was most marked on the organisms of Asiatic cholera, typhoid, and pneumonia. Some have inferred that smoking is of value in the prophylaxis and treatment of such diseases as diphtheria.

Arguments in favor of the use of tobacco on this or similar grounds have little weight. Its great value, after all, is the pleasure and mental satisfaction it affords. That tobacco is of great service to humanity in this way there can be no doubt. Most military writers admit that it is of value to soldiers, helping to pass the time in monotonous camps and acting as a nervous sedative in times of hardship and anxiety, as well as preventing the sense of hunger when food is scarce. Socially it has objections on account of its odor and in the habit of promiscuous spitting. It need not be expensive. Used in moderation by healthy adults it will seldom do serious harm. Surely it should not be classed with alcohol and morphine, but more properly with tea and coffee. The commonest of the more serious injuries are those having to do with the heart and the eyes.

The *prognosis* of the functional disorders resulting from over-indulgence in tobacco is good. They usually disappear promptly on ceasing the habit. If organic changes have taken place the prognosis is more grave. Thus the general or coronary arteriosclerosis, if such a lesion does result from tobacco, will not improve. The amblyopia usually recovers completely if proper treatment is instituted early enough; but, if the habit is persisted in, a high grade of ocular deficiency may become permanent.

Treatment.—Physicians should do all in their power to prevent the excessive use of tobacco, especially by women and young persons. Moderation, or better abstinence, should be observed by persons convalescing from acute diseases, those suffering from anæmia, gastric disorders, cardiac abnormalities, especially myocarditis, and other depressed states, even though they may have previously smoked with impunity. The combination of alcohol and tobacco is especially dangerous. Smokers will decrease the dangers if they will use pipes with long stems and keep them well cleaned. Notoriously strong tobacco should be avoided. The smoke should not be inhaled. Cigars should not be smoked too close to the end, nor held too long in the mouth. "Cold smoking" and chewing the ends of cigars are to be avoided. Athletes in training should avoid tobacco. Farvarger advises smoking only after meals. This decreases the quantity of tobacco smoked, and any irritating saliva which is swallowed comes into less intimate contact with the mucous membrane of the stomach.

When any of the symptoms of chronic tobacco poisoning appear, especially if the heart, nervous system, or eyes are affected, the habit should be given up entirely. This is difficult, but there is no particular danger in sudden withdrawal as "abstinence symptoms" do not occur in the same sense as they do after sudden withdrawal of alcohol or morphine. Abstinence must be prolonged, since, when symptoms have once begun, they are prone to recur. Alcohol must also be absolutely forbidden. Other predisposing conditions should receive attention. An abundant supply of easily digested food should be given and fresh air and general tonic treatment instituted.

For drugs strychnine is of value in full doses. Iodide of potassium is also recommended for the amblyopia. Tobacco angina and the other cardiac manifestations are to be treated by rest, small doses of digitalis and other heart stimulants, iodide of potassium, nitroglycerin or inhalations of amyl nitrite as in the same conditions from other causes.

TOLENAS SPRINGS.—Solano County, California

These well known springs are located about five miles north of the town of Suisun in Solano County, adjoining the famous Tolenas onyx quarries. They are reached by rail from San Francisco or Sacramento to Suisun, and thence by stage over a good level road. The resort is 1,253 feet above the sea, and is pleasantly located. On a clear day the State Capitol, Suisun Bay and Valley, and many other points of interest are easily seen. There are nineteen springs in all at Tolenas, flowing between six hundred and seven hundred gallons per hour. The temperature of the water varies from 60° to

65° F. The springs have had a local reputation for over thirty years, and of late the water has been bottled and sold extensively all over the State. The resort is at this time in a very flourishing condition. Two analyses have been made, one by J. Hewston, Jr., and the other by Dr. Winslow Anderson. They show no important difference in their results. Following is Anderson's analysis:

One United States gallon contains (solids). Sodium chloride, gr. 194.16; sodium carbonate, gr. 46.93; sodium bicarbonate, gr. 6.45; sodium biborate, gr. 19.13; potassium chloride, gr. 6.47; potassium iodide, gr. 1.75; magnesium carbonate, gr. 11.58; calcium carbonate, gr. 49.80; ferrous carbonate, gr. 0.89; alumina, gr. 1.10; silicates, gr. 1.92; organic matter, a trace. Total solids, 340.18 grains. Free carbonic acid gas, 31.27 cubic inches. Temperature of water, 61.5° F.

Hewston's analysis shows 360 grains of solid matter to the gallon. The water is warmly indorsed by many who have used it. In chronic skin affections, eczema, scrofula, and syphilitic infections it seems to act well. Chronic gastric disturbances, kidney and bladder diseases also improve under its use. The water is gently aperient and strongly diuretic. *James K. Crook.*

TOLIPYRINE.—This substance differs from antipyrin only in the substitution of the methyl group, CH_3, for one atom of hydrogen in the phenyl group. It is a white crystalline powder very similar to antipyrin in its physical as well as its therapeutic qualities. The indications for its use are the same as those for antipyrin, the dose being somewhat less—one part being equal to one and a half parts of the older drug. Its dose is given as from eight to thirty grains.

A salicylate of tolipyrine has been prepared to which the name of *tolysal* has been given. It bears the same relation to tolipyrine that salipyrine does to antipyrin. It is a crystalline, almost colorless (faintly pinkish) substance, lustreless, and with a bitter taste. In doses of fifteen grains every two hours it is said to be of much value in acute rheumatic attacks. *Beaumont Small.*

TONGUE, DISEASES OF.—In health the tongue varies greatly in appearance, but usually it is of a rosy-red color, moist, covered with minute papillæ (thread-like papillæ and larger round papillæ), free in its movements, and almost constantly changing in form. Very many persons, especially smokers and those engaged in such occupations as tea-tasting, have a more or less coated tongue even when apparently in perfect health. The volume of the tongue also varies greatly within normal limits. In some the organ is narrow and pointed at its tip, while in others it is large and flabby, with thick and rounded tip and margins which often show indentations made by the teeth. In nervous individuals the tongue is protruded quickly and as quickly withdrawn; in others of a more phlegmatic temperament the motions of the tongue, like those of the other voluntary muscles, are sluggish. In old age the tongue is almost always coated and is less moist than in youth, becoming often very dry and glazed upon the advent of even the slightest ailment. This is a point of some importance, for the physician called to see an aged person may be led to exaggerate the gravity of the condition if he take into consideration the evidence furnished by the state of the tongue alone.

The appearance of the tongue is not modified in every abnormal state, and it frequently presents no change in cancer of the stomach, or in gastralgia or enteralgia. It also often presents a normal appearance in simple jaundice, nasal catarrh, and many other slight ailments unaccompanied by fever.

Movements.—The movements of the tongue are sluggish in all adynamic conditions, in mental hebetude, and when the organ is dry. In paralyses of various kinds the muscles of the tongue are often affected and then the organ lies like an inert mass in the mouth, and cannot be protruded. In paraplegia one side of the tongue may be paralyzed, and then, when protruded, it deviates toward the paralyzed side, being pushed that way by the sound muscles. A trembling of the tongue is seen in adynamic conditions, in alcoholism, lead poisoning, and paralysis agitans, and when the individual is under the influence of various emotions, such as fear, anger, etc. Fibrillary contractions are sometimes observed in progressive muscular atrophy, in general paralysis of the insane, and in locomotor ataxia. Convulsions involving the lingual muscles have been observed in hysteria, epilepsy, and chorea, and in tuberculous meningitis in infants.

Coating.—A furred tongue is usually the condition which attracts the most attention. This occurs in many conditions, and the presence of a fur is almost always indicative of some abnormal state. In perfect health the tongue is clean, as a rule, although some seemingly healthy individuals have an habitually furred tongue. A thin whitish coating is almost always seen also in smokers. The fur is ordinarily composed of mucus, epithelium, particles of food and micro-organisms. It is due to increased production of the epithelium, owing possibly to reflex hyperæmia, or to any cause which prevents the removal of the cells normally cast off. When normal secretion is interfered with, as in fevers or in adynamic conditions, there is less chance for the detached epithelia to be washed away, and the coating is further increased by the collection of the inspissated mucus. A dry tongue is almost always coated, and when the mouth is open the dust collects from the atmosphere and helps impart a brownish tinge to the fur. Sometimes, when the fur is light or when the papillæ are enlarged, the latter project above the surface of the coating as little red points, presenting the appearance known as "strawberry tongue." This is seen in its most typical form in scarlet fever, and is recognized as one of the diagnostic points of that affection; it is also commonly present in Rötheln.

In dyspepsia the red fungiform papillæ will be seen to slope toward the tip, while in scarlatina they stand erect, their rounded summits suggesting the nodular surface of the fruit.

The fur is variously colored in different conditions, and these various colors often furnish valuable diagnostic indications. Thus, a thin white coating indicates febrile disturbance, or slight indigestion; a yellowish tinge points to hepatic disturbance; and a dry, brown fur, except in mouth-breathers, is usually a sign of profound dyscrasia. The fur may be moist or dry, the former condition prevailing in apyretic gastric disturbances, the latter in marked febrile conditions which have persisted for a long time and in which the vital forces of the patient are greatly depressed. In such states the tongue becomes covered with a thick, dry, brown or blackish coating, which is often furrowed and cracked, being perhaps partially detached in places, and showing a deep red color beneath. In disordered digestion the coating is thick, moist, and often brownish in color. A sign of some importance in the diagnosis of gastric ulcer from cancer of the stomach is the presence of a coated tongue in the first-named affection, and its absence in the second, unless there is fever. A clean tongue in the early stages of a continued fever should cause the physician to hesitate in making a diagnosis of typhoid fever. A hemorrhagic coating results from the imbibition of the coloring matter of the blood. It is usually accompanied by great dryness of the tongue, and the blood escapes from the fissures in the mucous membrane which result from the contraction of its epithelial covering. In diphtheria a false membrane occasionally, though rarely, forms on the tongue. As the coating is often the result of hyperæmia of the tongue, it may be seen in local diseases of the organ, and frequently a yellowish fur forms on one side in consequence of the irritation caused by a carious or broken tooth. In certain cerebral affections, especially in apoplexy, the tongue is covered with a thick sticky fur, and it is also coated and foul in chronic alcoholism.

Color.—In anæmia and allied conditions the tongue is pale, as it is also after profuse hemorrhages and in wasting diseases. In various diseases, such as icterus, Addison's disease, etc., the tongue participates in the general pigmentation and approaches the skin in color. The tongue is abnormally red in scarlatina, in inflammatory fevers, and often in the beginning of smallpox. A red, moist tongue indicates debility, such as occurs in consequence of long-continued exhausting discharges. In chronic conditions affecting permanently, in a measure, the digestive organs, the tongue is often intensely red, more or less dry, and sometimes presents a glazed appearance, as if varnished. In gastritis and in inflammation involving the other organs of digestion, the tongue is ordinarily redder than normal, dryish, narrowed, and pointed; sometimes it is furrowed and becomes of a brownish-red color. It presents a more or less purplish venous hue in all cases in which there exists an impediment to the circulation, or in which there is interference with hæmatosis. Thus we see this color in many cases of heart disease, in cholera, in croup, in pulmonary affections causing asphyxia, and when large effusions are present in the pleural or abdominal cavities. In malarial fevers the tongue is often purple at its margins, and in plethoric conditions the same venous hue is generally present.

SURFACE.—Normally the upper surface of the tongue is somewhat convex, and is slightly rough from the projection of its papillæ. When moderately dry it is smooth and presents a glazed appearance from the presence of inspissated mucus. When very dry the epithelium contracts and the surface is marked by rhagades of greater or less depth. Fissures of the tongue, without any furring, dryness, or change in color, are sometimes observed to occur in gastric disturbances. In some individuals, however, the organ is normally fissured even when moist. In syphilis the tongue is often ulcerated and fissured, and after healing there remain persistent whitish cicatrices. Wounds of the tongue caused by the teeth are seen in epilepsy, and may be of considerable diagnostic value in cases in which the convulsions are nocturnal.

An *impetiginous stomatitis*, in which the tongue, along with the buccal surface of the cheeks and lips, is covered with a tenacious exudation, and at times fissured, has been described by Sevestre and Gaston.[1] It occurs in debilitated infants with gastro-intestinal diseases, measles, pertussis, and impetigo. The Staphylococcus aureus was found in eight cases.

MOISTURE.—The tongue is moistened by the secretion of its glands and by the saliva. In ptyalism there is an increase in the secretion of the lingual as well as of the salivary glands. A return of moisture is a favorable sign in adynamic conditions. Dryness of the tongue is constantly present in a slight degree in some individuals, in whom it seems to be a normal condition. It is noticed in obstruction of the nasal passages, and in dyspnœa (phthisis, pneumonia, heart disease, etc.), when the patient is compelled to breathe rapidly and through the mouth. Certain drugs, such as belladonna, cause dryness of the tongue as well as of the other mucous membranes of the head. Long-continued speaking also induces dryness of the tongue, and the same condition occurs as a result of fasting. In prolonged febrile conditions, especially when the temperature remains constantly at a high elevation, the secretions of the tongue become diminished. In acute inflammation of the abdominal viscera, in intestinal obstruction, etc., and in typhoid conditions, the tongue becomes very dry, and often fissured. Such a condition indicates that the vital forces are ebbing.

VOLUME AND FORM.—The tongue is swollen oftentimes when there is interference with the return circulation of the head in consequence of heart disease, pulmonary affections, or compression of the veins of the neck from any cause. In chronic diseases of the chylopoietic system the organ is often considerably enlarged and indented. In idiots and in those suffering from certain mental affections the tongue is often large and flabby. In general paralysis, in paraplegia, and sometimes even in hemiplegia, the organ is large, soft, and flabby, its dimensions being such as sometimes to prevent closure of the mouth. In anæmia the tongue is broad and flabby, and shows the marks of the teeth. A similar condition is seen in smallpox, typhus fever, scurvy, and various blood dyscrasiæ and in mercurial poisoning. Inflammation with turgescence of the organ occurs as a result of the local action of certain irritant and corrosive poisons.

A broad, flat, square tongue, nearly filling the mouth, points to myxœdema. In acromegaly, too, the organ may become so enlarged as to prove of serious inconvenience. Abnormally long tongues have been described as malformations.

Enlargement occurs, too, from œdema, which, among other conditions, is seen in *stomatitis epidemica*, an affection in which the excessive swelling may be followed by necrosis. Enlargement is encountered also in urticaria, and occasionally it is due to quinine.

Changes in the shape of the tongue are owing, in many cases, to the absence of moisture, the organ becoming frequently concave on its upper surface from contraction of the dried epithelial layer. According to Gubler, there is a contraction of the transverse muscular fibres in fevers, so that the organ is less broad than normal. In hemiplegia the shape of the tongue is altered in consequence of the unilateral paralysis. The affected side is soft and flat, and after a time may become reduced in volume.

ARTIFICIAL DISCOLORATIONS may have diagnostic significance.

Rigal gives a table showing that black discoloration may be produced by ink, iron, mulberries, and some kinds of cherries; yellow by saffron, laudanum, rhubarb, nitric and chromic acids; red by rhatany, quinquina, and citrate of mercury, etc.; grayish-white by sulphuric, carbolic, and oxalic acids; white or pearl-gray by nitrate of silver and corrosive sublimate.

Corrosive acids, blackberries, tobacco, and rhubarb must also be mentioned as common discoloring agents. Caustic potash produces a gray and gelatinous appearance.

Tea-tasters are said to acquire a smooth, orange-tinted coating.

DEFORMITIES of the tongue may be either congenital or acquired, and consist principally in a complete absence of the organ, a split or bifid condition, a chronic state of prolapsus, hypertrophy, atrophy, adhesions, etc.

Aglossia.—Absence of the tongue has been recorded as a congenital condition in a case seen by Jussieu,[2] and in one mentioned by Förster[3] and as the result of disease in a number of recorded cases.

Atrophy of one-half the tongue, with nodules near the root, was observed by Lewin. The tongue deviated toward the affected side, and could scarcely be projected or elevated to the palatine vault. There was great difficulty in chewing, swallowing, and in pronouncing the letters *d, t, l, n,* and *r*. At the autopsy two gummata were found in the cranial cavity; one situated directly upon the hypoglossal nerve. Such cases may also, but more rarely, be due to peripheral causes.

Hemiatrophy has also been described by Ballet,[4] who says it may be the first evidence of central disease.

Atrophy of the whole organ is very rare compared with that of one side. The affected side in hemiatrophy is noticeably decreased in size, shrivelled up, and the mucous membrane covering it is thrown into folds. Atrophy of the whole tongue may follow a bilateral paralysis of the organ.

Hemiatrophy can be produced in the dog by cutting the sensory portion of the trigeminus. It may follow lesions of the intramedullary and intra- and extracranial hypoglossus. As a progressive condition it has been observed in facial hemiatrophy, possibly depending upon a low type of degenerative neuritis. It has been noted in a number of patients having locomotor ataxia, and the drawn up ridges on one side may be among the earliest signs of that disease.

Adhesions of the tongue, causing the common tongue-tie or bridled tongue of infancy, are not very rare. Ankyloglossus is another term which has been applied to this congenital condition when due to an abnormal development in breadth of the mucous fold beneath the tongue, called the frænum, or to its too high attachment.

All movements are restricted and suction is almost impossible.

Adhesions causing more or less complete immobility can also be due to accident.

Lateral adhesions have been noted as a congenital condition, and also as a consequence of mercurial gingivo-glossitis, noma, scurvy, etc. In all of these cases section with scissors is advised.

Children may be born with the dorsum of the tongue attached to the roof of the mouth, but such instances are exceedingly rare.

Bifid, or *split tongue*, a normal condition in some animals and birds (the seal and raven), has occasionally been seen. Barling reports a case of congenital division of the tongue with a median lobe.

HYPERTROPHY.—Though a predisposition to hypertrophy probably exists in many cases, it seems to be determined by some acute process, such as abscess or ranula, or one of the exanthemata. When of large size the organ protrudes from the mouth, the saliva constantly flows, the gums swell, and the teeth become loose. It must not be confounded with acute glossitis, with mercurial stomatitis, nor with tumor in the substance of the tongue.

Virchow describes the hypertrophied tissue as forming a lymphatic cavernous tumor, and it is now the accepted theory that the lymph vessels are dilated and the connective tissue is increased, but the muscular tissue is not hypertrophied. There appears, however, to be a form of muscular hypertrophy which constitutes a separate disease. Billroth says there is a fibrous form. In some cases the blood-vessels as well as the lymphatics are enlarged.

As regards treatment, Freteau has had good results from the application of a bandage in such a manner as to make even pressure from the tip backward. A cure may be effected, so long as the organ does not protrude, by applying pressure in the manner recommended by Butlin, *i.e.*, by inducing the patient to keep the mouth constantly and firmly closed upon the tongue. The application of a bandage to the mouth aids in the accomplishment of this purpose.

Hypertrophic Cicatrix.—False keloid is almost as rare as true keloid upon the tongue. Gevert [5] has presented an instance following a burn.

Hypertrophy of follicular glands in the posterior portion of the dorsum near the papillæ vallatæ, and in the sinus epiglotticus, is often attended with some inflammation, causing the sensation of a foreign body in the throat, with its attendant symptoms of "hacking," attempts to clear the throat, irritative or pertussis-like cough, painful or discomforting deglutition, dyspnœa, asthmatic attacks, and voice tire.

The finger may detect the swelling, and the laryngoscope shows the reddened and swollen follicles lying over the epiglottis and in the glosso-epiglottic fossa.

Hypertrophy of the lingual tonsil in the adult may reach such a degree as to suggest a new growth or polypus. To remove the adenoid vegetations a snare, linear écraseur, sharp spoon, or caustics may be used. Repeated applications of iodine often give good results.

Hypertrophy of Papillæ.—Because of the papillary nature of the surface of the organ hypertrophic enlargement of papillæ is not uncommon. This may, in rare instances, implicate a single papilla, more commonly, however, a small group of papillæ is involved, a wart-like tumor, or *papilloma*, resulting. Such a growth sometimes represents a congenital condition.

When a papilloma of the tongue has existed for some time it may become firm, verrucous, and even horny. At times the whole dorsum is studded with hypertrophic papillæ, giving an open, fig-like appearance.

In the same way hypertrophied filiform papillæ, when kept erect by the action of the teeth, may stand out like small porcupine quills. The *x* ray has a decided effect on the reduction of papillary hyperplasia and overgrowth and I have removed a large-sized papillary tumor by its exclusive use.

Hypertrophy of Pigment.—In Addison's disease dark or black colored areas are found near the tip of the tongue. The pigment lies in the deep cells of the epidermis. In jaundice the tongue is yellow. I have observed that the fungiform papillæ, which in the white races are pale or red, have naturally a brown, bluish, and sometimes black color in negroes, Indians, and dark-skinned Cubans. Maynard found that thirty-two per cent. of coolies had pigmented tongues. At times each fungiform papilla will be found surrounded by a bluish or brownish rim. Dark spots are found at times in melanosis and in malarial cachexia.

Prolapsus Linguæ.—In a few rare cases the tongue has been found too long, so that it constantly protruded from the mouth. This condition is also found as a result of hypertrophy and inflammatory action, and must not be confounded with the rarer congenital increase in length.

FUNCTIONAL DISTURBANCES.—The tongue is protruded with difficulty in low fevers, apoplexy, and sometimes in paralysis; in the latter condition the sound muscles force the tongue over toward the paralyzed side, and there may be loss of tactile sense. In chorea there may be a positive inability to protrude the tongue; it may be constantly thrust far out of the mouth. Here, as in epilepsy, the tongue is often bitten by the patient, and deforming scars may result.

Abnormal mobility of the tongue.—When at birth the frænum is too long, it has happened that the infant has swallowed the tongue or drawn it so far back as to cause suffocation and death. This may also happen after dividing the frænum. Treatment consists in replacing the tongue with the finger, and exercising care in feeding. There has been reported a case in which the patient, who experienced much inconvenience from the accumulations of mucus on the posterior wall of the pharynx, succeeded in cleansing the naso-pharyngeal cavity with his tongue. The frænum, in this case, was found ruptured in several places.

Ageusia and *parageusia* are derangements of the special sense of taste, which is lost for such substances as sugar, salt, acids, etc., in the first, and perverted in the second. Ageusia of an incomplete character is seen in some facial paralyses and in hysteria. It may also result from injury of the trigeminus or the glosso-pharyngeal. Both conditions may arise from irritation of the nerves of taste, and be a symptom in catarrhal diseases. Perverted taste is also seen in hysteria.

Treatment. Antiseptic and stimulating mouth washes and electricity. If the cause can be found and removed, the taste will speedily return.

Anæsthesia of the tongue may interfere with its functions. There may be gustatory anæsthesia or a loss of ordinary sensation in the tongue. This, like paralysis, may be due to a central or a peripheral cause. Loss of taste may depend, according to Butlin, upon failure of conduction in the nerves of taste.

Glossoplegia.—Paralysis may affect the muscles of one or of both sides of the tongue. That of one side alone has been observed by Lewin and others. One case, accompanied by symptoms almost identical with those of a bulbar paralysis, recovered promptly under corrosive sublimate injections. If due to cerebral lesion, glossoplegia will be apt to be attended by the same symptoms of headache, dizziness, etc. In hemiplegia of the body, the tongue is protruded, as I have already said, toward the affected side, and this is also true of monoplegia. I have seen a woman paralyzed on both sides, whose tongue lay as an inert body in the floor of the mouth, the ragged borders quivering when an ineffectual effort was made to protrude the organ, which had become atrophied from disuse. Speech was wholly impossible, and mastication very difficult.

Glossoplegia is the initial symptom in progressive bulbar paralysis, with indistinct speech and feeble protrusion of the tongue. Later on, the dorsum becomes furrowed and wrinkled. Galvanism to the neck may benefit. When the condition is due to intracranial disease, and also when it is perhaps associated with hemicrania, even though there may be no evidence of lues, iodide of potassium freely given may be of great benefit.

Hyperæsthesia of taste is seldom met with, but pain located in the tongue alone is quite common. Aside from the pain attending many diseases, elsewhere considered, we have some rare neuralgias limited to this organ, and, as a rule, to one side only.

Spasm of the Tongue.—*Clonic spasm* is a rare affection observed by Erb and others. The tongue may be protruded involuntarily, being pushed forward against the dental arch, or it may show involuntary muscular contractions on one or both sides. Clonic spasm is seen in hysteria and in the epileptic seizure. Bromide of potassium and electricity are recommended. The condition may be looked upon as a neurosis of the hypoglossus.

Chorea-like movements, limited to the tongue, have been reported as occurring in hemiplegia to the extent of interfering with speech. The movements grow less as the paralysis improves.

Tonic spasm is seen in hysteria, and in other conditions, probably due to reflex irritation.

Unilateral spasm of the tongue has been observed by Wendt. The attacks would last for several minutes at a time, the right half of the organ becoming suddenly hard and contracted by repeated twitchings. The patient recovered under galvanism.

INFLAMMATORY CONDITIONS.—The causes which may be active in producing inflammations of the tongue are multiple. Thus it may follow a great variety of injuries, bites and stings of insects, and the application of irritant substances, and it may be found in eruptive and other fevers. It may be acute or chronic. When deep-seated, inflammation of the tongue may endanger life through suffocation, and in the acute form its onset is often sudden and may end in pus formation, and the subsequent abscess may press upon the epiglottis and thus also threaten life.

In two instances I have seen glossitis result from the accidental taking of ammonia. The tongue, under these circumstances, is first made white, becomes much enlarged and painful, and then subsequently casts off its coating of epithelium. In one of the cases referred to, the patient, who was a sufferer from asthma, mistook the hartshorn for the whiskey bottle at night, and by the time I reached him the thickened tongue filled and protruded from the mouth, causing difficulty of breathing, which, added to that of the asthma, was distressing in the extreme.

Abscess of the tongue may be the result of acute inflammation of the tongue; in such cases it is deeply seated, and has been mistaken for cancer, the tongue having been removed on account of it. The more chronic forms are usually circumscribed and deep-seated, and may occur without preceding glossitis or herpes. The swelling is firm and elastic, and there is no superficial discoloration, so that it may readily be mistaken for a cyst. The abscess is generally situated toward the anterior portion of the tongue, near the edge, and is usually very chronic. An exploratory puncture quickly clears up the diagnosis when fluctuation is not clear or "pointing" is delayed. Treatment by longitudinal incision rapidly brings the case to a favorable conclusion.

Early operation to prevent suffocation is sometimes indicated, though spontaneous cure after rupture occurs in most cases; and if the patient is seen early the application of ice and cooling lotions or emollient washes prevents the more serious condition.

Actinomycosis now and again occurs as a primary disease in the tongue, developing as a deep-seated inflammation of the base, with a wood-like hardness of the entire suprahyoid region. The occupation of the patient may lead to suspicion, and confirmation will be found in the discovery of the characteristic yellow granules. As is well known the tongue, in actinomycosis in herbivorous animals, is frequently affected with nodular swellings of various sizes; and as the affection is becoming more and more frequent in man, and as infection usually takes place by way of the mouth, it will not be surprising if tongue cases become more numerous.

Anthrax.—Malignant pustule occurs in connection with lesions upon the external surface, or, in the œdematous form, upon the tongue with formation of pustules. It occurs also in rare cases as a primary lesion, as reported by Rammstedt.[9]

Chancroid may begin as a reddened tissure, to be followed by ulceration and attended with submaxillary adenopathy.

Syphilis.—The most common form in which the syphilitic poison manifests itself upon the tongue is that of the mucous patch. The primary sore may occur upon the tongue, and in the later stages we have the gummy tumor and ulceration, fissures, plaques, and tertiary ulcerations. Men are more prone to suffer relapses than women, probably owing to their greater use of tobacco and alcohol.[10]

Chancre of the tongue is commonly located at or near the tip. It may run its course before a diagnosis is made. Chancre is apt to be hollowed out, bowl- or crater-shaped, with sides gently sloping to the centre, while a tuberculous ulcer has irregular borders and base, and shows granulations which make it uneven, while here and there at the periphery are little yellow points somewhat suggesting miliary abscesses. From chancroid it is recognized by its red or rosy color, while the latter has a yellow base.

Condylomata as well as papillomata are found in syphilis; the distinction between the two being that the former are more flattened and, besides the hypertrophy of papillæ, there is a tumefaction of the intervening tissue making a more firm or solid as well as a more flattened tumor.

Gummata, which may be confounded with primary sclerosis, occurs upon the surface or within the substance of the tongue. They are rather late manifestations. Nodules the size of a pea or smaller occur upon the posterior part of the dorsum, and might escape notice if they remained unirritated. When single and laterally situated, beginning cancer is simulated. Those located within the parenchyma are not so easy of diagnosis. They may reach the size of a large hickory nut and are not very sensitive. For some reason they occur most often in men. Carcinoma is single and situated at the border, while a gummy tumor is apt to be multiple and more centrally located. Chronic abscess of the tongue is more clearly defined than gumma.

Treatment by large doses of iodide of potassium almost invariably brings about speedy resolution and cure, and this may at times prove of value as a diagnostic test. Locally, nitrate of silver stick, lightly applied, will in most cases soon cause them to disappear. If this does not act well, a solution of chromic acid (strength of from ten to fifty per cent.) will almost always bring about a rapid cure.

Cysticercus cyst of the tongue is more frequent than the echinococcus. The diagnosis is established only on incision or after suppuration. Though the occurrence of this parasite in the tongue is common in animals it is certainly rare in man. In one case the larva of the Tænia solium was found upon incision of a painful tumor of the tongue.

Echinococcus disease involves the tongue in rare instances. The diagnosis can be made only after incision or by the coincident involvement of other parts.

Diphtheria at times presents patches upon the tongue; never, however, unless the throat is coincidently affected.

Erysipelas involves the tongue by extension from neighboring parts. Primary erysipelas of the tongue has been reported by a number of observers, but while some maintain that the organ does not become tumefied, others describe the swelling to be of such a size as to render it impossible to close the mouth.

Erythema Exudativum Multiforme.—Lesions of the exudative form of erythema occur at times upon the tongue, but the quickly rupturing bullæ would be difficult of recognition were no lesions present on the skin

Since this affection likewise is apt to recur, it has been confounded with recurrent herpes of the tongue.

Herpes, in connection with the same disease, upon the face, lips, etc., is a not very uncommon condition. Actual vesicles are naturally present for only a very short time, and when the patient is seen a red, inflamed, tender, and somewhat indurated area shows where the primary lesions were situated. It is found almost wholly upon the tip and edges of the tongue.

For treatment, the application of powders containing acacia, bismuth, prepared chalk, etc., frequently repeated, or of borax in honey by means of a camel's hair pencil, acts beneficially, and when the parts are less tender, borax, alum, or tannin washes may be used.

Aphthous sore mouth often begins as a vesicular eruption.

Keloid is among the great rarities. Sedgewick[7] describes an instance seen in a young girl who had, besides the tumor on one side of the tongue, true keloid on various parts of the body. There was slow extension toward the tip of the organ.

Lepra may produce lesions upon the tongue quite similar to those which occur upon the integument. Campana saw in a leper boy a group of small papilliform tumors, that formed an oval plaque as large as a twenty-five-cent piece, slightly elevated, and with a rough surface. Some of the separate tumors were conical in form and some rounded. They had a rose color and were painless. Characteristic bacilli were found in one which was removed and examined microscopically.

A microscopical section through a leprous tongue showed bacilli collected in groups and in ball-like masses.

Lichen planus, it would appear, not infrequently causes tongue lesions which would present difficulties of diagnosis were the skin lesions absent. Erasmus Wilson first pointed out the possibility that lichen may develop upon the tongue, with roughness and the formation of round whitish patches. Jonathan Hutchinson subsequently observed lesions consisting of small papules. Neumann reports papules similar to those of psoriasis of the mucous membrane, being flattened and lentil-sized. Touton mentions a case in which the tongue was covered with flat, round, grayish-white plaques. Pospelow saw lichen planus papules which were flat and without central atrophy.

The lesions of the tongue may be more or less extensive at the time when the cutaneous eruption is first observed, or the tongue lesions may precede or follow those of the skin. In most cases the lesions occupy the mucous membrane of the cheeks and of the lips at the same time, though I have observed one patient in whom the lichen lesions were limited to the tongue and the glans penis. They occur as sharply defined white spots, rounded or slightly irregular, without marked projection above the surface, isolated or joined in groups, or as parallel lines along the borders of the tongue. Thibierge[8] thinks we must look upon these as lesions of lichen planus, although they do not itch.

According to Unna, the lichen ruber of Hebra is also accompanied by mouth lesions. In a case observed by him, there were lesions upon the tongue in the form of multiple erosions, which were altogether different from the plaques of lichen planus.

Lupus is rarely found on the tongue without having previously existed on the face, larynx, soft palate, or nose. It occurs mostly upon the back part, near the epiglottis, more rarely upon the tip, as small isolated nodules, with soft granular surface; star-shaped cicatrices result. Leloir, Clarke, and others have observed primary lesions here located, and Spires[8] records fourteen observations in connection with lupus elsewhere. The tip in one case was completely destroyed. It was probably inoculated from lupus upon the lips. In distinguishing the disease from tuberculous ulcer we have, as characteristics of the former, much less pain or entire absence of pain, and a much slower evolution.

Neuralgia of the tongue is a most distressing affection, and one difficult to eradicate without operation. Fortunately it is not common. I have observed one instance of it in a lady with arthritis deformans. The paroxysms are of short duration but of frequent repetition, and the attacks may come on at intervals of a few months. The pain is usually located along one border of the organ.

Papilloma of the tongue is an occasional cause of neuralgia, but more often the lingual nerve is affected. Daily scraping of the tongue has been accused of favoring its development. A rheumatic or other diathesis may be found as a predisposing cause.

Dubreuil reports a case in which he performed resection of the lingual nerve in a woman forty-five years of age, whose neuralgia had lasted for four years.

Nigrities Linguæ.—In black tongue the discolored area, is limited to the middle of the dorsum, as a rule, and the edges are not so black as the middle portion. The elongated oval area is limited at first, but slowly spreads. Desquamation usually follows. The affection may last weeks, months, or even years. The papillæ seem much longer and thicker than normal, and the color makes them appear still more prominent. Subjective symptoms are usually wanting. Many cases of so-called black tongue are undoubtedly accidentally or intentionally made black by iron, ink, or dyes. It has been observed under widely varying conditions. The blackness is marked and persistent, and invariably spreads from a small beginning; the color toning down from black to brown, and from the centre to the sides. Raynaud speaks of its resemblance to "a field of corn laid down by wind and rain."

Dessois[9] has described, under the name of glossophyton, a fungus found in the epithelial deposits and débris making up the black deposit upon the elongated papillæ. A black fungus of the class of Hyphomycetes, found by Schmiegelow, has been thought to be the cause.

The treatment consists in frequent applications of peroxide of hydrogen on absorbent cotton. Friction with Hebra's spiritus saponis, followed by mild salicylic ointment, or a five-per-cent. salicylic solution in ether, with the addition of five-per-cent. collodion to form a thin coating when painted on the affected areas, has been found the most efficacious by Brosin.

Pemphigus has been known to occur upon the tongue, and well-marked bullæ distended with fluid have even preceded the eruption upon the skin in the acute form. The pain is here greater than in the lesions of pemphigus vulgaris. The diagnosis must usually be made from the coincident eruption upon the skin, since the bleb almost at once is transformed into an erosion. Menzel believes that pemphigus can exist upon the tongue in the form of reddened plaques without actual bullæ.

Periglossitis sublingualis, or inflammatory œdema of the cellular tissues about the tongue, is an exceedingly rare condition, of which Henoch has recorded one instance. There is pain and difficulty in speaking and eating. The cause is unknown.

This list of affections of the tongue comprises most of those which possess some importance, but the limited amount of space which has been alloted to this topic compels me to omit a number of less important diseases. For information regarding them the reader will have to consult one of the larger monographs on the subject.

TONGUE, SURGERY OF THE.—INJURIES OF THE TONGUE.—*Burns and Scalds.*—The tongue is not uncommonly the subject of injury from burns and scalds. Slight burns or scalds are of but little consequence, the superficial portion of the covering of the tongue only being destroyed; in a few hours, or, at most, at the end of a day or two, the tenderness disappears without treatment. To relieve the pain, applications of sweet oil, borax and honey, bicarbonate of soda, or astringent lotions, are useful. The most severe burns are those caused by chemical agents, such as mineral acids, caustic alkalies, corrosive sublimate. When these substances have been accidentally or intentionally swallowed, the tongue is not the only part that suffers, for the whole of the interior of the mouth, the fauces, and the throat are also affected. It is often possible to recognize the poison taken by the appearance of the tongue. In poisoning by corrosive sublimate the tongue is white and shrivelled. Carbolic acid renders the mucous membrane white and hard. Vegetable poisons, as a rule, produce no alteration in the appearance of the tongue in cases of acute poisoning (Butlin).

Scalds of the tongue are not uncommon in young children, and are often produced by sucking the spout of a tea kettle. This accident is more common in England than in this country. The injury to the tongue in such cases is of small importance compared with the grave complications which arise from injury to the larynx and air passages. The tongue swells, becomes red, and is soon covered with blisters; it is of course tender and painful, and food in any form is difficult to take. This difficulty, however, soon subsides, and is of little moment compared with the grievous results which follow injury to the air passages.

Effects of Cold.—In winter, in this country, one occasionally sees an injury to the tongue in children produced by cold, and this, although it is not dangerous, is sufficiently painful. It is generally caused by the child licking with the tongue iron or other metal at a low temperature. In such cases the tongue adheres to the metal, and the child, pulling the tongue quickly away, leaves behind a considerable portion of the mucous membrane. The writer has frequently seen this accident happen to children playing out of doors when the thermometer registers a temperature considerably below the freezing point. On one occasion several children were induced by a mischief-loving companion to place their tongues on an old iron pot, the result being that each one was deprived of a large amount of the covering of the tongue and suffered considerably, especially during meals, for several days afterward. The treatment of such cases is the same, of course, as that of burns.

Stings of Insects.—In England it is not uncommon for insects, such as wasps and bees, to be taken into the mouth, concealed in fruit, and serious inflammation has resulted from their stings. In such cases Fairlie Clark [1] recommends that the mouth be frequently washed with an alkaline solution to neutralize the formic acid. A weak solution of ammonia is very efficacious.

Wounds.—Usually wounds of the tongue are not serious, but Bryant,[2] of London, mentions a case in which death followed a wound of the tongue, in a small child, from trickling of blood down the larynx, the child dying asphyxiated. Wickham Legg[3] relates cases of death following bites of the tongue in persons the subjects of hæmophilia.

Wounds of the tongue may be produced in various ways, but most commonly the wound is caused by the teeth. Epileptics not infrequently bite the tongue severely during a fit. The tongue may be severely wounded by a fall on the chin, or by a violent blow on the jaw when the tongue is protruded. The protruded portion of the tongue may be completely bitten off, or one side only be injured. Injuries to the tongue may be caused by dentists' forceps while the patient is under the influence of an anæsthetic.

The hemorrhage resulting from injury to the tongue is seldom dangerous, and is usually easily controlled by ice or exposure to air. Should the hemorrhage be profuse, its source should be sought for and the bleeding vessel, usually the ranine artery, tied. Oozing from the wound is generally arrested by bringing the edges of the wound together with sutures. In certain cases in which the wound is far back, it may be necessary to pass a ligature through the tip of the tongue to draw it out, and to examine the wound thoroughly; if it be small, then it should be enlarged and the bleeding vessel secured. In some cases it may be necessary to use the cautery to arrest the hemorrhage, its use, however, interferes with primary union. Sutures are not necessary if the wound be small, but if it be large and a portion of the tongue is hanging loose, then the edges of the wound should be carefully brought together with deeply placed silk or catgut sutures. A case is related by Mr. Gant in which the tongue was severed by an incised wound extending nearly through the substance of the organ, and dividing the lingual and hypoglossal nerves on both sides. The detached portion, which hung by a mere shred on the left side, was replaced promptly and secured, complete union took place, and the tongue slowly recovered power of motion and the sense of taste. The after treatment of wounds of the tongue is similar to that of other wounds of the mouth. The mouth should be washed out frequently with weak Condy's fluid, or a paint of iodoform and alcohol may be used.

Wounds of the tongue may be caused by foreign bodies, such as the stem of a tobacco-pipe, crochet needles, splinters of wood, etc. Foreign bodies are occasionally driven into the tongue in cases of gunshot wounds; these consist of teeth, portions of the jaw, etc.

Foreign bodies have been found embedded in the tongue months and years after the accident. A case is related of a soldier who was shot in the face at the battle of Gross Goerschen, in 1813; the bullet passed through the cheek and tongue, carrying away some of the molar teeth; the wound in the tongue quickly healed; in 1845, thirty-two years after, the tongue became swollen and discharged the second molar tooth which had been carried into it by the bullet in 1813.[4] Manget relates the case of a patient in whose tongue a ball had been lodged for six years. During this time the man stammered excessively, but when the ball was extracted, the stammering ceased.[5]

When a wound of the tongue does not readily heal, or when there is secondary hemorrhage, then a foreign body may be suspected; or again, if a sinus exists and an indolent swelling remains, it is very probable that a foreign body is present. When the foreign body is removed, the wound usually heals up. According to Butlin,[6] the removal of the foreign body does not always bring about such a happy result; in more than one case this procedure has been followed by hemorrhage which has caused death.

A case is related of a sailor, aged thirty, who was keeping watch on deck, and at the same time smoking; he either fell or struck against some object by which the pipe in his mouth was driven into his tongue and broken. There was at first but little apparent injury and only slight hemorrhage, but subsequently the tongue began to swell, and on the fourth day he was taken to the London Hospital. His mouth was closed, and he had swallowed little or nothing since the accident. There was swelling at the upper and back parts of the neck; the tongue was enormously enlarged and fluctuating. An incision was made, and an ounce of purulent fluid, mixed with blood, escaped. This gave some relief, but the symptoms soon returned with greater intensity than before. A probe was then passed into the tongue by the opening made with the lancet, and something hard was felt in the deep substance of the organ. This was grasped with forceps and extracted; it proved to be a piece of pipe stem four inches long. Immediately after its removal a frightful torrent of blood gushed from the mouth and nostrils, and the man was dead in little more than a minute. At the autopsy it was found that the pipe stem had entered the right side of the tongue near the tip, passed just below the left tonsil, and completely transfixed the left carotid artery and internal jugular vein.[7]

TONGUE-TIE, or shortness of the frænum linguæ. The tongue is bound down and cannot be protruded beyond the incisors. This is a congenital defect which is not uncommon, and when it exists to a high degree it prevents the child from suckling, and later may interfere with articulation. In such cases it is necessary to divide the tightened band; this should be done with a pair of scissors with blunt points. The points should be directed to the floor of the mouth to avoid wounding the ranine arteries. Cases are on record of fatal hemorrhage occurring from accidentally cutting these vessels. In dividing the frænum only a small cut is necessary, and then the rest may be torn through with the fingers. This even is generally unnecessary, for the child, in crying, still further frees the tongue. Petit[8] draws attention to another danger of cutting too freely. He relates three cases in which vigorous sucking in strong and hungry children tore the wound in these tissues still further open, so that the tongue, losing its anterior attachment, turned back and was embraced by the muscles of deglutition, and pressed the epiglottis firmly over the larynx until suffocation was produced. Two of the cases ended fatally before help could be afforded.

The frænum may be congenitally too long, and cases of death from suffocation have been recorded owing to this condition, the patient swallowing the tongue. A number of cases are reported in which by constant practice the patient has acquired the habit of tongue swallowing.

MACROGLOSSIA.—This is a congenital hypertrophy of the tongue analogous to elephantiasis. It is of slow development, and as the tongue enlarges it causes great trouble, the mere size interfering with deglutition and speech. The tongue may protrude over the chin and reach even as far as the sternum. The subjects of this affection frequently suffer from epilepsy. The great enlargement causes deformity of the teeth and jaws, especially the lower. The teeth frequently become carious and fall out, and the lower jaw has been known to have been dislocated by the pressure.[9] There is constant dribbling of saliva, and the protruded tongue is much altered in appearance, indurated, swollen, and purplish in color; later, nodes, irregularities, and fissures appear on its surface, and occasionally the tongue ulcerates. On puncturing it there is not much bleeding, but there is oozing of large quantities of serum. The disease is not, as a rule, noticed for the first two years, as sucking appears to stop the growth of the organ by continuous pressure. The pathology of this disease was first elucidated by Virchow; he found that there was an overgrowth of interstitial connective tissue, with a remarkable infiltration of the whole organ with white cells collected here and there in a delicate network, and forming true lymphoid tissue. The disease, no doubt, is due to congenital defect aggravated by frequent attacks of glossitis.

Treatment consists in removal of the protruded portion of tongue. In some cases the removal of a V-shaped portion will give the best results. Strapping with plaster has occasionally been successful, but excision is the best method of treatment. A few years ago a German surgeon reported a case in which great improvement occurred in a child aged thirteen months, treated by Pirogoff's method, viz., ligature of the lingual arteries.[10] This is an old method of treatment which years ago was tried and found wanting.[11] Ligature of the portion of tongue protruded has been successfully practised, but nothing is so safe or simple as excision with knife, galvano cautery, or écraseur. The hemorrhage usually is not great, and the result is almost invariably satisfactory. When bleeding is feared in young children, the removal by écraseur should be preferred, but in adults the knife or scissors is better, as their use is not followed by sloughing. The tongue should be drawn forward by means of ligatures passed through its substance behind the line of incision, and the incision should be made in such a manner that the tongue will be left somewhat pointed; the bleeding vessels should be tied as cut. The after-treatment is the same as that used for partial removal of the tongue for any other cause.

In a case of this kind in which I removed a large portion of the tongue a number of years ago, the result has been excellent, the patient now having an almost normal tongue, and speaking with great distinctness and facility.

TUMORS OF THE TONGUE.—*Vascular Tumors.*—Nævi are occasionally found in the tongue; if superficial, they may be treated by nitric acid or by puncture with thermo-cautery needles. When the growth is prominent and can be isolated, it may be excised with scissors or treated by ligature. When a nævus growth is treated by excision, the healthy tissue should be cut all around, the hemorrhage then being inconsiderable. If there is much danger of hemorrhage, the thermo cautery knife may be used. When the growth is large and more diffuse, excision by means of the wire écraseur is a valuable method of treatment; the écraseur should cut through healthy tissue. Ligature is seldom necessary in such cases, but when used it should be passed deeply into the substance of the tongue and tied very tightly.

Sir Joseph Fayrer has described[14] an affection called *cirsoid aneurism* of the lingual vessels. It simulated ranula.

Cystic tumors of the tongue are not uncommon. They may be due to dilatation of the mucous follicles, and contain a gelatinous mucus.

Sebaceous cysts occur in the tongue but very rarely; they should be treated by excision.

Fatty tumors are sometimes met with, and are usually of small size and easily removed.

Enchondromata have been described by Weber.[15]

Sarcomata of the tongue are almost unknown as primary growths.

Keloid has been noticed by Sedgwick.[16]

Fibrocellular tumors of the tongue have been described by Mason,[17] Clarke,[18] and others. They occur mostly in adults and may be congenital; these tumors are situated on the dorsum of the tongue and are quite painless and innocent. Treatment should be by excision.

Papillomata or *warty tumors* occur on the dorsum of the tongue, and consist merely of hypertrophied papillæ. Butlin[19] describes a case in which there was warty enlargement of all the fungiform papillæ. The diagnosis is easy when the affection occurs in early life, but when it exists in old people it is sometimes difficult to diagnose from epithelioma.

Treatment.—Removal by scissors is the simplest and best mode of treatment when the growths are small; when they are large, ligature is more satisfactory. If there be any induration at the base or the slightest suspicion of the growth being malignant, then, to insure its complete removal, the healthy tissue around should be excised as well as the growth. Butlin[20] states "that the treatment of the larger and doubtful warts, in persons over forty years of age, by caustics and other similar measures, cannot be too strongly deprecated." The writer has frequently seen commencing epitheliomas in middle-aged persons treated for several months by caustics, under the supposition that the case was one of warty growth; such treatment increases the rapidity of the growth if cancerous, and lessens the chance of a cutting operation being successful.

Ulceration of the Tongue.—Ulceration of the tongue may be simple, syphilitic, tuberculous, cancerous, or mercurial.

Simple ulcers may be due to irritation from a sharp tooth or to traumatism of any kind. We may have a simple ulcer as the result of long-standing superficial glossitis. Dyspeptic ulcers of a superficial character are not infrequently met with, also aphthous ulcers. These are more common in children than in adults, and general treatment by salines, combined with astringent lotions of alum or tannin, is often of great benefit. Borax and chlorate of potash washes are also useful. In treating simple ulcers the removal of the cause is generally sufficient to cure the disease. If the ulcer does not heal readily, Butlin[20] recommends the frequent painting of the surface of the sore with a solution of chromic acid (gr. x. to ℥ i. of water), or with a lotion of borax (ʒ ss.), glycerin (♏ xx.), and water (℥ i.). Burning these ulcers with nitrate of silver, especially in the old, is not to be recommended, as the irritation caused may induce a cancerous condition in those predisposed. Should the ulcer not heal rapidly under simple treatment in a man over forty years, then cancer is to be suspected, and the ulcer should be cut out. A simple operation of this kind may save the patient much future trouble.

Tuberculous ulcers usually occur on the tip of the tongue. When extensive, they are difficult to diagnose from cancer. The ulcer is irregular, with sharp-cut edges or pale flabby granulations at the base. There is very little induration of the surrounding tissue. The ulcer in its advanced stages may eat deeply into the tongue. It is generally acutely painful, so much so that the lingual nerve has been divided to ease the sufferings of the patient. In the late stages there is considerable salivation. A tuberculous ulcer of the tongue may be the primary manifestation of tubercle, or it may occur secondarily. *Primary* ulcers are rare, *secondary* more common. The writer has seen several cases which were secondary to ulceration in the larynx and tuberculous disease of the lung. When the ulcer is primary the diagnosis is difficult. From syphilitic ulcer it may be distinguished by the history; syphilitic ulcers are usually on the central part of the tongue, and if due to gummata they are preceded by local swelling. With tertiary ulcers the glands are never affected, with tuberculous ulcers they are frequently enlarged. A tuberculous family history and the existence of tubercle bacilli will help one to a correct diagnosis.

The *diagnosis* between carcinoma and tubercle is more difficult still, for in both affections the lymphatic glands are involved. The age of the patient and the existence of extensive induration would point to cancer. Cancer does not usually occur under the age of thirty. A difficult case presented itself to the writer quite recently: a young girl, aged twenty-two, with a decidedly tuberculous family history, had extensive ulceration of the right side of the tongue with slight induration, and with involvement of the lymphatic glands of that side; the ulcer was painful to the touch and there was considerable salivation. A portion was excised and under the microscope it presented the typical characters of epithelioma; no bacilli were found in this case. The patient declined operative interference.

The *prognosis* of tuberculous ulcer is quite as unfavorable as that of cancer, and the patient succumbs to the disease in from a few months to two years.

Treatment.—An endeavor should be made to relieve the pain by soothing lotions, etc. Papaitine often relieves pain, and according to some it is curative, but this the writer cannot indorse. Scraping with a sharp spoon and then painting with tincture of iodine has been advised.

Butlin[22] strongly recommends excision when possible, even if the ulcer be secondary, as both a painful disease and a focus of further infection are thereby removed. Great relief has followed the application of the following: finely powdered iodoform, gr. i.; morphine, gr. $\frac{1}{6}$; borax, gr. iij. The surface of the ulcer should be cleansed and dried before application, and the powder should be applied three or four times a day. Should the pain be intense and confined to one side, division of the lingual nerve must be thought of. General treatment by cod-liver oil and tonics should not be omitted.

Syphilitic ulceration commonly occurs during the secondary stage of syphilis, along the edges of the tongue. The ulceration is superficial, and a white patch on the mucous membrane of the cheek, corresponding to the ulcer of the tongue, will nearly always be found. Fissures or cracks which plough up the dorsum of the tongue in every direction are peculiar to syphilis; these are usually the result of tertiary syphilitic ulceration, single cracks or fissures are sometimes seen in the secondary variety. Superficial syphilitic ulcers have no induration at the base. Mucous tubercles or patches may also appear on the tip and borders of the tongue during the secondary stage, but at the same time they exist on the lips, vulva, and anus; they are oval or round in shape, grayish in color, and covered with partly macerated epithelium.

The *deep syphilitic ulcer* is caused by the breaking down of a gumma, and is usually situated on the dorsum of the tongue. It has sharp-cut edges which may be undermined, the base is sloughy and ragged, and there are always some induration and swelling of the neighboring parts.

Diagnosis.—These cases are difficult to diagnose from cancer; however, the history of the case and the situation of the ulcer will help one to form an opinion. If syphilitic, such ulcers are preceded by a lump; in cancer the induration follows the ulcer and does not precede it. There may be two or more gummata on the tongue, but a cancerous ulcer is always single. Cancerous ulcerations occur more commonly on the side of the tongue, syphilitic on the dorsum. In tertiary syphilis the glands are rarely enlarged; in cancer which has existed for some time the lymphatic glands are always enlarged. Syphilitic ulceration yields to antisyphilitic treatment. Many cases, however, occur in which the diagnosis is very difficult and can be settled only by the microscope.

It must be borne in mind that the primary lesion of syphilis may occur on the tongue, the infection being usually due to inoculation from secondary sores. The occurrence of a primary sore on the tongue is rare, and presents the appearance of primary sores in other parts. The submaxillary lymphatic glands are usually enlarged from the first. In the superficial forms of secondary syphilitic ulceration the treatment should be constitutional as well as local, viz., mercury internally, in the form of gray powder, with local application of half a grain of bichloride of mercury to one ounce of water. Butlin speaks highly of chromic acid as a local application (ten grains to one ounce of water), applied three or four times a day.

In the tertiary syphilitic ulcer, iodide of potassium in doses of from ten to twenty grains three times a day, largely diluted, combined with tonics, will effect a rapid cure; local applications other than those of a soothing character are rarely necessary. Syphilitic ulcers always leave scars; the puckered and furrowed scar left behind by a deep ulcer is characteristic.

Cancerous Ulceration.—This form of ulceration of the tongue is always of one variety, viz., epithelioma. It generally commences as a small ulcer on the side of the tongue, though no part of the tongue is exempt. The posterior half is, however, much less commonly affected than the anterior half. In eighty cases collected by Butlin,[23] cancer affected the sides and borders of the tongue in seventy-one. It occurs more frequently in men than in women; according to Barker,[24] in the proportion of two hundred and forty-seven to forty-six. It will be found, on examining the various statistics, that cancer of the tongue occurs more frequently between the ages of forty-five and fifty-five. Billroth[25] states that it is more common between the ages of fifty and sixty, and such has been the writer's experience. It very rarely occurs in young adults. Barker mentions a case at twenty-six years of age. The writer has seen one case in a woman, twenty-two years of age, in which the diagnosis was verified by the microscope.

There is no doubt that smoking predisposes to cancer of the tongue, as many cases are preceded by leucoma or the so-called psoriasis of the tongue. This condition may be produced by dram drinking, smoking, and also by syphilis. In eighty cases collected by Butlin,[26] sixteen were preceded by leucoma. The psoriasis and scars produced by syphilis, injury, or any other cause, will predispose to cancer; any irritation such as a sharp tooth, the stem of a tobacco-pipe, a bad-fitting tooth plate, etc., will in some persons excite ulceration which may take on a cancerous action. The writer saw one case of epithelioma of the hard palate in an old man, produced by the irritation of the stem of a clay pipe, which continually rested at that point owing to the toothless condition of the gums. There is no doubt, however, that cancer of the tongue may originate without any pre-existing disease or irritation, but in the majority of cases some form of irritation is the exciting cause of the disease. Many practitioners who are consulted by elderly people for ulcers of the tongue are in the habit of cauterizing the sore freely with nitrate of silver or other caustic; this is a most pernicious custom, and one which, while it does no good, may do infinite harm; for, should the ulcer be cancerous, it only aggravates it, and it may excite cancer in an ulcer which is of a simple, non malignant character, by the continued irritation. Again, it does harm in cancerous ulcers by putting off operative measures until a period when operation can be of but little use, by soothing the patient with the idea that something is being done for him. Ulceration of the tongue in people over forty years of age should always be regarded with suspicion, and if there be any doubt as to its nature, the ulcer and a portion of healthy tissue around it should be excised. When the cancerous ulcer is well developed, or the induration at its base is marked, the diagnosis is not so difficult, but if there be any doubt a portion should be excised, and the microscope will usually establish the character of the disease.

Pain is an early and characteristic symptom, not always in the tongue, but in the lower jaw, gums, ear, and sometimes the back of the head. Salivation is also often an early symptom. When the ulcer commences on the border of the tongue it rapidly infiltrates not only the tongue, but the floor of the mouth and the gums, and finally the bone of the jaw itself is affected. The tongue becomes fixed and its motion is so limited that it cannot be protruded. Should the disease begin farther back, the ulceration or infiltration extends to the pillars of the fauces, soft palate, and tonsils. These cases have proved fatal from hemorrhage caused by ulceration into the internal carotid or tonsillar arteries. When the disease has advanced thus far the glands in the neighborhood become enlarged. First, there is tenderness in the submaxillary region, with pain which shoots up to the ear; later, the glands may be felt small and hard but movable; as they increase in size they become fixed. In some cases, in the early stages of the disease, the glands may be affected, yet the fact may not be recognized by external manipulation. The first glands to become affected are the submental in the floor of the mouth, then the submaxillary, afterward the carotid at the bifurcation of the arteries, and finally the parotid. Of course the glands are involved on the same side as the cancerous disease. When the tip of the tongue is the part involved the submaxillary glands and suprahyoid glands are first affected. There are several lymphatic glands embedded in the submaxillary salivary gland. If the root of the tongue be ulcerated, then usually the parotid lymphatic glands near the angle of the lower jaw and the carotid glands are first affected, making the case a much more serious one. The lymphatic channels between the disease and the glands are usually free, a condition, according to Heidenhain, common to epitheliomata. As the disease progresses deglutition and speech become difficult, there are profuse salivation and a horrible fœtor of the breath. Patients may die from hemorrhage due to the growth ulcerating into some large vessel, or there may be frequent hemorrhages from smaller vessels which may hasten the end. The usual mode of death, however, is from exhaustion due to pain, sleeplessness, starvation, sloughing, etc. The average duration of the disease in patients who have had no operation is from a year to eighteen months. Many cases succumb in less than a year, and few live longer than two years.

Diagnosis.—In the advanced stages of cancerous disease of the tongue the diagnosis is not difficult; the foul, deeply excavated ulcer with everted ragged edges and widely infiltrated base, with large granulations protruding from it, the pain, the fixation of the organ, and the induration of the submaxillary glands, stamp the affection unmistakably as carcinoma. At this stage operation is not very hopeful.

The diseases with which carcinoma of the tongue are most likely to be confounded are: (1) Syphilitic ulceration, primary and tertiary; (2) tuberculous ulcer.; and (3) simple ulcer. The differential points of diagnosis between these diseases and cancer have been sufficiently dwelt on above. The writer would strongly urge that when the diagnosis is doubtful, the disease should be treated as cancer and removed; for, should the surgeon wait until all doubt is dispelled by the involvement of the glands and the infiltration of the surrounding tissues, then he has committed a grave fault, and one which cannot be repaired. Butlin[27] truly says: "Medical men are coming to the belief that, to 'give the patient a chance,' means usually to give the carcinoma a chance of obtaining a firm and irresistible hold, and to take all chance of complete recovery from the patient." It is much better to remove a suspicious wart or ulcer by a simple and safe operation, and thus save the patient from the ravages of a fatal disease, than to wait until the disease is pronounced, when to operate means not only great danger to the patient, but the certainty of a rapid recurrence of the disease.

Prognosis.—Cancer of the tongue, like cancer of other parts, if not operated on, proceeds invariably to a fatal termination. It is of the utmost importance that the disease should be recognized in its early stages, when it is a purely local affection. At this period, if operation by removal of the tongue be undertaken, the chances of the patient remaining free from the disease are greater, and should the disease recur the interval of freedom is much increased.

Treatment.—There is but one method of treatment of cancer of the tongue, viz., removal by surgical operation. Operation always relieves, if it does not cure. In Butlin's table of 80 cases already referred to, 70 were operated on, and 9 patients were in good health a year after the operation. Heath reports a case well eleven years after operation. Dr. Fenwick, of Montreal, reports a case in which the patient lived fifteen years after operation. Bryant,[28] of London, mentions a case well ten years after operation, and one in which the disease recurred fifteen years after operation. Barker[29] found 17 recoveries in 170 cases. According to Billroth's[30] statistics, 14 per cent. of cases are cured after operation. Even such a small percentage of cures is very creditable to surgery, and would in itself more than justify removal; but, putting aside the cures, the patient's life is prolonged and suffering is diminished by operation.

With regard to other methods of treatment by caustics, pastes, etc., they are not only useless but hurtful. It cannot be too strongly insisted on that the treatment of cancerous ulcers by caustics is bad treatment, and that the only chance the patient has of a cure is in the early removal of the disease by surgical operation. In cases of ulcers, warts, etc., on the tongue of a person over forty years of age, in which the diagnosis is doubtful, if any treatment is desired previous to removal, it should be of a soothing, non-irritating character; all irritating substances, as tobacco, spirits, highly spiced foods, etc., should be avoided. If the sore is produced by a sharp tooth this should be extracted. Caustics should be shunned, as nothing is more likely to convert a simple into a cancerous ulcer than continual irritation by caustics.

Operations for Partial and Complete Removal of the Tongue.—Small warts, whether they are on the border, tip, or dorsum of the tongue, are most easily removed with curved scissors; no anæsthetic is required. Should the growth be of larger size and far back it is better to anæsthetize the patient and place a gag in the mouth; then the tongue may be drawn out by a strong ligature passed through the tip, or by means of a vulsellum. The growth should be removed with a knife and the bleeding points secured with ligatures or arrested by the thermo-cautery. Some surgeons advise the use of the galvano-caustic loop, as by this method all fear of hemorrhage is banished and the tissues for a short distance round the base of the growth are destroyed.

Removal of a Portion of the Tongue.—Should the cancer of the tongue be confined to the tip or a small part of the border of the anterior half of the tongue, and should the submaxillary glands not be enlarged—in other words, if the ulcer be early recognized to be cancer,—the removal of a portion of the tongue is justifiable and gives a fair chance to the patient, without submitting him to the much more formidable operation of excision of the whole tongue. Partial removal of the tongue may be performed with galvano-écraseur, thermo-cautery, knife, or scissors. Czerny of late years has frequently used the thermo-cautery, and he thinks there are fewer recurrences after this method of treatment than when the knife is used. Roediger (*Beiträge zur Klin. Chirurgie*, vol. xxxi., 1901) also strongly recommends it, and says that after its use there was no fever, œdema, or secondary hemorrhage. The knife is to be preferred when it is necessary to remove only a small part of the tongue. Should the ulcer be on the border of the tongue, then the tongue should be split in the median line and the affected half removed with knife, scissors, or écraseur. In all operations on the tongue of any magnitude the mouth should be kept open with a suitable gag, such as Coleman's, Whitehead's, Hutchinson's, etc., and the tongue drawn out by a stout ligature passed through its tip, and the disease removed by the method recommended by Mr. Baker.

Baker's Method.[31]—A gag having been introduced, the tongue is drawn out by means of two ligatures placed one on each side of the median line of the tongue near the tip. The tongue is then split down the middle and the diseased half is freed from the floor and side of the mouth with scissors. Needles are now passed through the tongue behind the disease, and the loop of the écraseur is placed as far back as possible, tightened, and the affected half removed. The loop of the écraseur should be of wire or whip-cord. The objection to the use of the galvano-cautery is the troublesome slough which follows.

Removal of the Whole Tongue.—In cases in which the cancerous ulcer involves the posterior half of the organ or is very extensive, it is necessary to remove the whole tongue. The complete removal of the tongue is the better operation, even when the ulcer is small, for the chance of recurrence is much less than when only part of the organ is taken away.

In removing the tongue one of the chief dangers is from hemorrhage, and before proceeding further it might be as well to mention a very simple and efficacious method of arresting hemorrhage, occurring either accidentally during operation or afterward. This method was introduced by Mr. Heath, of London, and has been adopted by most surgeons. It is this[32]: "The forefinger, passed well down to the epiglottis, is made to hook forward the hyoid bone and drag it up as far as practicable toward the symphysis menti. The effect of this is to stretch the lingual arteries so as to completely control for a time the flow of blood through them, and in this way portions of the anterior part of the tongue may be cut off almost bloodlessly." In operating on the tongue for cancerous disease, the question arises as to the kind of operation which should be performed. After even the most radical operation the disease is apt to recur; in fact, the more severe the operation, as a rule, the more rapid the return of the disease. Some surgeons hold that the operation is merely palliative, especially if the glands are enlarged in the submaxillary region and under the sterno-mastoid. In such cases, they advise simply a removal of the tongue and non-interference with the glands.[33] Others again, as Kocher, hold that the extirpation of the diseased glands cannot be too thorough, and they in every case make an incision in the neck to search for enlarged glands, which cannot be found by external manipulations. They argue that if the glands in the axilla are removed in all cases of excision of the breast for cancer, it is quite as important to remove the submaxillary lymphatic glands in operation for cancer of the tongue. It is a simple enough operation to remove a portion of the tongue with the écraseur; the recovery from the operation is rapid, but so is also the return of the disease. In cases between the ages of forty-five and sixty a radical operation, with extirpation of the glands, is the proper one, but in cancer in old people approaching seventy years of age the case is different, and a simple removal of the tongue will probably be as successful as a most complete and radical operation. When there is extensive involvement of the glands of the neck, the case is hopeless and operation should be undertaken for the relief of the patient only, as it is impossible to remove all the disease in such cases.

Operations for the removal of the tongue, or part of the tongue, are much facilitated by dividing the cheek horizontally from the angle of the mouth to the border of the masseter muscle; this incision gives much more room and the scar left is insignificant. Jaeger first advocated this method, and Gant and Furnaux Jordan practised it in Great Britain. This procedure does not add to the risk of the operation, and it gives the operator greater facility for arresting hemorrhage.

Removal of the tongue through the mouth by the écraseur or scissors, without a submental incision, is only suitable in those cases in which the disease is limited to the anterior part of the tongue and when the glands are not involved; or it may also be practised in those cases in which the degree of gland infiltration is so great that extirpation is hopeless, and the tongue is removed purely for the purpose of relieving the patient from great suffering. In all other cases some form of submental operation should be practised, for then the enlarged glands can be easily reached and removed, and the chance of a permanent cure is much increased if the glands be extirpated. The points to be kept in view in operations on the tongue for malignant disease are: (1) The possibility of removing all the disease; (2) the prevention of hemorrhage; (3) the avoidance of the entrance of blood into the air passages; and, after operation, (4) the preservation of an aseptic condition of the mouth and secretions until healing is complete. In order to accomplish this, some form of submental operation is necessary. Operations involving division of the jaw are more serious, are disagreeable to the patient, and delay convalescence.

The operations which have been practised for the removal of the whole tongue are very numerous. The most popular operation with English surgeons at the present day is that known as Whitehead's, viz., removal of the tongue by scissors; this may be done with or without preliminary ligature of the linguals. A few years ago nearly every surgeon employed the galvanic or wire écraseur, but the occurrence of secondary hemorrhage when the slough separates is so frequent that the écraseur is much less popular with surgeons than formerly, and has been supplanted by the scissors. With scissors the entire tongue can be removed easily and simply.

Whitehead's Method.[34]—"1. The mouth is opened to the full extent with Mason's or any other suitable gag, the duty of attending to this important part of the operation being entrusted to one of the two assistants required.

"2. The tongue is drawn out of the mouth by a double ligature passed through its substance an inch from the tip. This ligature is given in charge of the second assistant, with instructions to maintain throughout the operation a steady traction outward and upward.

"3. The operator commences by dividing all the attachments to the tongue, to the jaw and to the pillars of the fauces, after the manner suggested by Sir James Paget, with an ordinary pair of straight scissors.

"4. The muscles attached to the base of the tongue are then cut across by a series of successive short snips of the scissors, until the entire tongue is separated on the plane of the inferior border of the lower jaw, and as far back as the safety of the epiglottis will permit.

"5. The lingual or any other arteries requiring torsion are twisted as divided. It is generally found that a moment's pressure with a piece of sponge held in sponge forceps, suffices temporarily, if not permanently, to arrest any bleeding; it is, however, regarded as desirable to twist, either immediately or after the tongue is removed, every bleeding vessel.

"6. A single loop of silk is passed by a long needle through the remains of the glosso-epiglottidean fold of mucous membrane, as a means of drawing forward the floor of the mouth, should secondary hemorrhage take place. This ligature may with safety be withdrawn the day after operation, and, as it is invariably a source of annoyance to the patient, it is always desirable to adopt this rule.

FIG. 4726.—Incisions for Operations on the Tongue. *a*, Incision through the cheek, after Jaeger; *b*, von Langenbeck's incision, with division of the jaw; *c*, incision for removal of glands and ligature of lingual arteries as practised by the writer.

"The after-treatment consists in feeding for the first three days absolutely and solely by nutrient enemata, satisfying thirst by occasionally washing out the mouth with a weak iced solution of permanganate of potash; forbidding any attempt at speaking, and requiring that all the wishes of the patient shall be expressed in writing or by signs. The difficulties and dangers of the operation are few and more imaginary than real. Hemorrhage, the *bête noire* of most surgeons who contemplate removing the tongue, is in reality easily controllable and frequently trifling. I have twice removed the entire tongue without having to secure a single vessel, and more than once have only had to twist one lingual artery." The operation practised by the writer is that commonly known as Billroth's, viz., excision of the tongue by scissors with preliminary ligature of the linguals. This operation enables the surgeon not only to avoid danger from hemorrhage, but also to remove the neighboring glands and structures which are involved in the disease through the same incision made for ligating the lingual arteries. In Billroth's operation the mortality is not greater than that following other operations.

Billroth's Operation.[35]—The head of the patient having been well thrown back and the chin turned to the side opposite to that on which the artery is to be tied, a curved incision is made from near the symphysis menti to near the angle of the lower jaw, the convexity downward, having its lowest portion running along the upper border of the great cornu of the hyoid bone. A careful dissection is then made through the platysma and deep cervical fascia, and if any veins are cut they should be ligatured before proceeding further with the operation. The tendon of the digastric muscle should now be searched for, and in the angle which this tendon forms with the hyoid bone, the artery will be found—but not immediately, for covering it we have the hyoglossus muscle with the hypoglossal nerve and ranine vein running over it. The hyoglossus muscle should be carefully divided, and then, all bleeding having been arrested by Pean's forceps and ligatures, the artery is felt pulsating at the bottom of the wound. Hemorrhage should now be completely arrested and the artery being brought into view can be easily tied. The artery on the opposite side having been secured in the same way, any glands that may be involved should be looked for and removed through these incisions in the neck. As a rule, they can be found without difficulty. It is a good rule to remove all the submaxillary lymphatic glands as well as the submaxillary salivary gland on the same side as that in which the cancer is. It is well before clearing the submaxillary space to ligate the facial artery.

The mouth should now be kept open with a gag and the tongue drawn out by a double ligature passed through its substance about an inch from the tip. The operator, holding the ligature in his left hand, draws the tongue outward and upward and removes it with a straight pair of scissors. The attachments of the tongue to the jaw and pillars of the fauces should first be freed and then the muscles at the base, and now, the attachment to the hyoid bone being divided with a few short cuts, the whole tongue will come away, leaving the epiglottis behind. The removal of the tongue takes, as a rule, only two or three minutes. If the tissues of the floor of the mouth be involved, they should now be attended to.

The wounds in the neck, which during the excision of the tongue should be filled with carbolized sponges, are then sewed up and dressed with aseptic gauze dressings. If the floor of the mouth has been removed it will be better to pass a large drainage tube into the mouth through the neck incision; in fact, this ought to be done in every case. The mouth is now packed with sticky iodoform * gauze and the operation is complete.

The after-treatment is the same as after excision of the tongue by other methods.

The advantages of the operation above described are many:

1. The diseased structures, and especially the glands, are discovered and removed with the greatest ease through the neck incisions.

2. The removal of the tongue is bloodless, and there is no fear of secondary hemorrhage.

3. The incision made by the scissors is a clean-cut one, and there is no bruising of the tissues as in the operation with the écraseur.

4. The tongue can be more completely and more easily removed with scissors than with any écraseur.

5. Drainage of the mouth can be more thoroughly carried out by means of the incisions in the neck.

6. The operation is easy of performance and few instruments are required, no more than every surgeon possesses, viz.: straight scissors, knife, and a few pairs of Pean's forceps.

Kocher's Operation.[36]—A still more radical and extensive operation than the one described above is the operation performed by Kocher, of Berne. It is the only operation for the removal of the tongue which aims at preserving the parts in a thoroughly aseptic condition. Tracheotomy is first performed and a well-fitting cannula introduced; the pharynx is then packed with a carbolized sponge with a cord attached, so that it can be easily re-

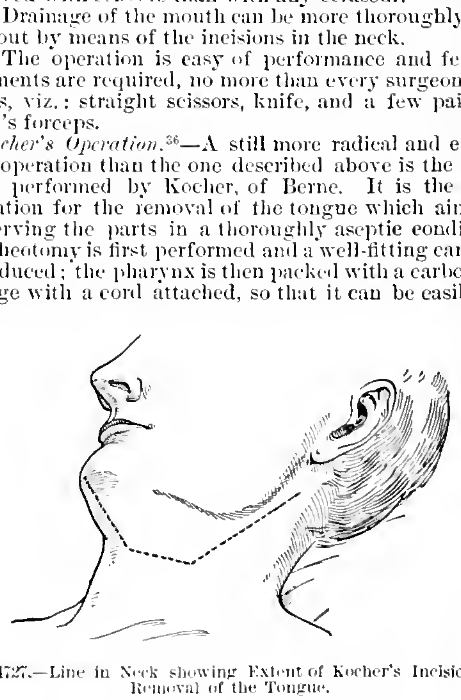

FIG. 4727.—Line in Neck showing Extent of Kocher's Incision for Removal of the Tongue.

moved when necessary. An incision is now made commencing a little below the tip of the ear and extending down the anterior border of the sterno-mastoid muscle to

* The sticky gauze is prepared with resin, alcohol, and iodoform. Weir, of New York, recommends the following formula as an improvement on that introduced by Billroth: Resin, 10 parts; castor oil, 6 parts; iodoform, 5 parts, and alcohol, 15 parts. This is rubbed into the gauze, and certainly, as the alcohol evaporates, it is sticky enough. The writer has, in cases in which the gauze failed to remain in the mouth, painted the surface over with the liquid.

about its middle, then forward to the body of the hyoid bone, and along the anterior belly of the digastric muscle to the jaw. The resulting flap is turned up on the cheek and the lingual artery is ligatured as it passes under the hyoglossus muscle. The facial artery and any veins that may be in the way are also secured. Commencing from behind, all the structures in the submaxillary fossa are removed, viz., the lymphatic glands, the submaxillary, and, if necessary, the sublingual glands. The opposite lingual artery is now tied by a separate incision if the whole tongue is to be removed. The mucous membrane along the jaw and the mylo-hyoid muscle are then divided and the tongue is drawn out through the neck incision, and removed with scissors or galvano-cautery; the latter is preferred by Kocher, as there is less liability to after-oozing. The after-treatment is most important; if the operation be an extensive one, the external wound should not be closed. Kocher's endeavor is to avoid the two great after-dangers of excision of the tongue, pneumonia and general septicæmia. To prevent the discharge causing infection, the whole cavity of the mouth and pharynx is plugged with carbolized sponges and iodoform gauze. The operation as first described was performed under the spray. The patient is fed by the rectum partly, but chiefly by the throat with a tube, twice a day, when the dressings are changed. Thus, if all the minute directions are enforced, the wound remains aseptic throughout, and no food or discharge from the wound can possibly enter the air passages. There is one thing that Kocher has not guarded against, and that is vomiting; should the patient vomit, as is so often the case after the administration of anæsthetics, the elaborate preparations against sepsis may come to naught.

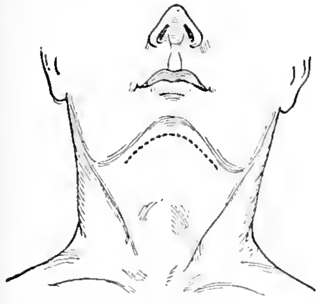

FIG. 4728.—Curved Line Below the Chin, showing the Extent and Situation of Billroth's Incision.

In Kocher's hands this operation has been most successful. He had one death in fourteen cases, eight recurred, one died a year afterward of pneumonia, one lived fourteen months, two five years, and one six and a half years.

With the modern methods of keeping the mouth aseptic, and performing all operations in the mouth with the patient in the Trendelenburg position, tracheotomy is rendered unnecessary. There is no doubt that it adds to the danger of the operation. The one death in Kocher's series of cases was caused by hemorrhage from the tracheotomy wound.

Billroth's modification of Regnoli's operation is very simple and much to be preferred to the original operation. The longitudinal incision is omitted and the curved incision is carried farther outward on each side, so that the linguals may be ligatured before removal of the tongue. It is a very suitable operation in those cases in which the submaxillary fossa is involved in the disease.

The tongue can be removed by scissors.

Removal of the Tongue after Division of the Lower Jaw.—This operation was introduced by Sédillot, of Strasburg, and afterward practised by Syme, of Edinburgh. It consists in making a vertical incision in the lower lip, sawing through the inferior maxilla at the symphysis, separating the two sides of the jaw, and drawing out the tongue and removing it by scissors, écraseur, or knife. The divided portions of the jaw are afterward wired together. It is a good plan to make the holes for the sutures before dividing the jaw.

Von Langenbeck[38] has advised a lateral section of the jaw opposite the first molar tooth. The skin incision is made from the angle of the mouth downward (see Fig. 4726). Division of the jaw adds to the danger of the operation, and makes it more unpleasant for the patient. Convalescence in these cases is usually prolonged. It is seldom necessary to divide the jaw in extirpating the tongue, even when the disease is most extensive, for the infiltrated glands in the floor of the mouth can be easily removed by one of the submental operations, with less danger and greater comfort to the patient. In some cases in which the disease has extended to the gums and bone itself, a portion of the jaw may require resection. It is often sufficient to remove the alveolar process only.

Occasionally, after removal of the tongue through the mouth, it is found that the glands in the submaxillary region subsequently become enlarged, although apparently healthy at the time of operation; then, if they appear movable and there is no recurrence of the disease in the mouth, a special operation for their removal is advisable. If, on the other hand, the glands are fixed and the tissues infiltrated, operation is of little avail. In cases of carcinoma in which the glands and the sterno-mastoid are first affected, operation is usually of little benefit.

Butlin[37] recommends that after removing part or the whole of the tongue, as the case demands, the surgeon should wait three or four weeks, and then by a separate operation remove the glands in the cervical, submental, and submaxillary regions. An incision is made along the anterior border of the sterno-mastoid muscle, from the mastoid to below the thyroid cartilage, and a second incision from the symphysis menti to the first incision about the level of the thyroid cartilage; the flap is lifted up from below and all the glands are removed, and then the flap is replaced and sutured.

The following list of operations, taken from Barker's article in "Holmes' System of Surgery" vol. ii., 1882, will prove of interest to the reader, and will serve to give him some knowledge of the history and progress of the operation of excision of the tongue.

EARLIEST IRREGULAR OPERATIONS.

1. *Pimpernelle.* Died 1658, was probably the first to excise the tongue with success.
2. *Marchetti*, 1664. Extirpated a cancer of the tongue by actual cautery; probably the first recorded extirpation for this disease.
3. *Val. Hoffmann*, 1692. Removed a tongue affected with macroglossia.
4. *Ruysch*, 1737. Excised tongue with knife.
5. *Memonista*, 1737. Cauterized with a hot iron.
6. *Heister*, 1743. Gave the first methodical description of operative treatment of cancer of the tongue.
7. *Burdorf*, 1754. Excised a true cancer of the tongue with knife.
8. *Guthrie*, 1756. Was probably the first English surgeon to excise a cancer of the tongue, using the knife, followed by cauterization of the cut surface.
9. *Louis*, 1759. Ligatured a fungus of the tongue, and in 1774 spoke in favor of total excision for cancer.

DEFINITELY DESIGNED OPERATIONS.

Ligature.

10. *Inglis*, 1803. Introduced ligature of the tongue from the mouth for cancer, the cords being drawn with needles through the tongue and round the tumor. (*Edin. Medical and Surgical Journal*, 1805, p. 34.)
11. *Major*, 1827. Split the tongue down the centre to apply ligature to the diseased half through the mouth.
12. *Cloquet*, 1827. Also split the organ, but introduced the ligature by suprahyoid incision and strangled the diseased half. (*Archives Gén.*, xii., 511.)

Wedge-shaped Excision.

13. *C. J. Langenbeck*, 1819. Introduced wedge-shaped excision of the diseased part of the tongue with careful suture of resulting flaps. ("Biblioth. f. Clin. u. Augenh.," Bd. 2, 187.)

Preliminary Ligature of the Lingual.

14. *Mirault*, 1833. Introduced preliminary ligature of lingual artery to give a clear, bloodless field for extensive incisions. He was followed later by Roux and Roser. (*Archives Gén.*, vi., 5, 656.)

Écrasement.

15. *Chassaignac*, 1854. Introduced the écraseur, employing Cloquet's suprahyoid method and defining it more exactly, *i.e.*, using puncture instead of incision. ("Traité de l'écrasem. lin., p. 31.)

16. *Middeldorpf*, 1854. Introduced the galvanic écraseur (*Schmidt's Jahrbücher*, Bd. 107, 260.)
17. *Nunneley*, 1856. Introduced the suprahyoid use of the écraseur into England. Adopting Chassaignac's modification. (*Med. Times and Gaz.*, 1862.)
18. *Girouard*, 1857. Employed circumpuncture with rods of caustic. (*Archives Gén.*, 1857.)

Division of the Cheek.

19. *Jaeger*, 1831. Was the first to divide the cheek for free access to the tongue. ("De Extir. Linguæ," 1831.)
20. *Maisonneuve*, 1858. Divided both cheeks from the angle of the mouth for same purpose.
21. *Collis*, 1867. Reintroduced Jaeger's operation, using the écraseur. (*Dub. Quart. Journ.*, xliii., 1867.)

Division of the Lower Jaw.

22. *Roux*. Died 1836. Was the first to divide the lower jaw and lip in mid-line in order to gain free access to the floor of the mouth and tongue. (Maisonneuve, Thèse, p. 146.)
23. *Sédillot*, 1844. Improved this method by dividing the bone by a serrated cut. (*Gaz. des Hôp.*, 1844, 83.)
24. *Syme*, 1857. Divided the jaw in mid-line and excised with knife. (*Lancet*, 1858, vols. i. and ii.)
25. *Billroth*, 1862. Divided the jaw and soft parts at the side in two places, and turned down the flaps of skin and bone so formed, replacing and wiring the bone afterward. (*Archiv f. Klin. Chir.*, 1862.)
26. *B. von Langenbeck*, 1875. Divided the jaw and soft parts opposite the first molar tooth on one side, in order to gain access to the side of the mouth for removal of tongue, glands, and part of palatal arch and tonsil.

Intramaxillary Operations.

27. *Regnoli*, 1838. Opened the floor of the mouth from below by an incision from middle of hyoid bone to chin, ending in another semilunar incision along the border of the jaw. The tongue was drawn through the opening and excised. (*Bull. Sci. méd. Bologna*, 1838.)
28. *Czerny*, 1870. Modified Regnoli's procedure, forming lateral flaps.
29. *Billroth*, 1871–76. Modified it still further, extending both ends of the curved incision much farther backward, and omitting the incision in mid-line. (*Archiv f. Klin. Chir.*, Bd. 16, Hft. 2.)
30. *Kocher*, 1880. Introduced a method of opening the mouth from behind and below the angle of the jaw to reach the base of the tongue and remove it with all the lymphatic glands situated there. (*Deutsche Zeitschrift f. Chir.*, Bd. xiii., 146, 1880.)

Results of the Operation.—The immediate results following excision of the tongue are fairly good, considering the severity of the operation. Whatever operation for excision of the tongue is practised, the mortality in a series of cases is about the same, so that the method of operating seems to have less effect on the result than the after-treatment. Still, certain operations are more favorable than others as regards the recurrence of the disease, and it is reasonable to suppose that when the disease is most completely removed it is least likely to return.

Whitehead in 139 operations had 20 deaths, or 14.3 per cent. Butlin [37] has collected 333 cases of excision of the tongue from the statistics of 4 operators, and finds that there were 42 deaths due to the operation. Of 202 uncomplicated cases only 14 died. In 109 cases in which there was either division of the lower jaw or excision below the jaw, the mortality was 25. About twenty per cent. of patients live three or more years after operation.

With regard to the *frequency of recurrence* it may be said that recurrence is the rule. Barker [39] has collected 170 cases in which the whole or part of the tongue was extirpated, and in only 17 cases was there non-recurrence after an interval of a year. According to the same author the duration of the disease, in cases not operated on, was 11.7 months, and in those operated on 19 months, a clear gain of 7.3 months. The longest period of freedom from the disease after operation seen by the writer was 28 months. It is to be hoped, with the modern methods of antisepsis which are now so universally practised, that the excision of the disease will be more complete, and hence the period of freedom from recurrence prolonged, and also the mortality after operations much decreased.

Dangers of Excision.—Formerly the danger most dreaded during and after operations on the tongue was hemorrhage, primary and secondary. Since the galvanic écraseur has been discarded, secondary hemorrhage is much less frequent, and both primary and secondary hemorrhage is avoided by preliminary ligature of the linguals. This procedure is a very simple one when the tongue is removed by one of the submental operations, as Billroth's, Kocher's, etc. Even should the linguals not be previously ligatured, there is usually little danger from hemorrhage, owing to the facility with which a bleeding vessel can be seized by the modern artery forceps.

The greatest danger connected with excision of the tongue is without doubt septic pneumonia, or other lung affection, produced by direct infection from the fetid discharges of the decomposing wound. In some cases there is gangrene of a portion of the lung, or numbers of small, foul, circumscribed abscesses; in others a condition of bronchopneumonia. Whatever affections of the lung ensue after excision of the tongue or severe operations on the mouth and jaws, they are all due, either to the inhalation of fetid gases from the sloughing wound in the mouth, or to discharges from the same source passing down the trachea to the bronchi and lungs. In other words, the lung affection is produced by direct infection from a foul wound. Barker [40] has collected 52 cases of death following operation; of these 30 were fatal from some pulmonary affection; 12 from septic affections, in 6 of which no mention is made of the condition of the lungs; and in the remaining 10, death was due to various causes, as shock, collapse, asphyxia, exhaustion, etc. The passage of blood into the trachea during operation is another cause of lung affection, and, to avoid this, anæsthesia should not be too profound. Usually symptoms of pneumonia and bronchopneumonia appear soon after the operation. The case may go on favorably for two or three days, then there is a troublesome collection of ropy mucus in the mouth and the wound becomes very fetid, cough is complained of, the temperature and pulse run up, respirations are very rapid, and the patient becomes cyanosed and dies in a few days with symptoms of pneumonia. The breath during all this period has been horribly fetid. The autopsy discloses acute congestion of the trachea and bronchi, and in the lungs are numerous small foul-smelling abscesses with, in places, patches of gangrene. Cases occur also in which the patient dies of simple pneumonia threatening to become gangrenous.

Treatment after Excision.—The most important point in the after-treatment is to preserve a condition of asepsis in the wound, for, as has been shown above, the greatest danger is due to direct septic infection from the wound itself. Again, the swallowing of blood at the time of operation, tainted with the foul discharges of the cancerous ulcer, should be carefully guarded against by having the mouth thoroughly and frequently washed out with some antiseptic solution, as Condy's fluid, carbolic acid, etc., before operation, and, during operation, avoiding a condition of too profound anæsthesia. After operation the wound in the mouth should be packed with sticky iodoform gauze as recommended by Billroth, painted over with alcoholic solution of iodoform and resin, or at least dusted with iodoform crystals. Billroth, as already mentioned, had seventeen cases of excision without a death or even a serious symptom, owing to the mouth being kept thoroughly aseptic by the packing with sticky iodoform gauze, which in a day or two becomes incorporated with the wound. The writer has found great difficulty in keeping the gauze in the mouth after the first day; he has found that it becomes loose and covered with mucus, and that the patient finds it very troublesome. He has used with good results the following paint, advocated by Weir, of New York, to impregnate gauze: Iodoform, 5 parts; resin, 10 parts; castor oil, 6 parts; and alcohol, 15 parts. When painted on, the alcohol evaporates and leaves the resin and iodoform behind coating the surface of the wounds. This should be painted on twice daily. The first three or four days after operation the patient should be fed entirely by the rectum, and occasionally allowed to rinse out his mouth with water to allay thirst. After this, feeding should be by the mouth through a tube introduced into the œsophagus. A very good arrangement is a soft catheter with a piece of rubber tubing attached to it, and to this again is attached a glass funnel; by pouring liquid food into the funnel the patient can be easily and comfortably fed. Should any fœtor appear in the wound, the mouth should be frequently washed out with a solution of Condy's fluid, carbolic acid, or chlorate of potash. Washing out is much facilitated if there is a drainage tube through the incision in the submaxillary region.

Palliative Treatment of Cancer of the Tongue.—The object is to relieve pain and lessen fœtor and salivation. To relieve pain, division of the lingual nerve is advised, and also the administration of opium. Fœtor and salivation may be controlled by frequent washings with some antiseptic solution, as Condy's fluid or carbolic acid, and afterward the dusting on of iodoform or salicylic acid. Bleeding, which so frequently terminates the case, may be controlled by styptics, or by lint soaked in tincture of the muriate of iron and kept continually pressed against the bleeding points with forceps. Should the bleeding be distinctly arterial, then ligature of the lingual artery of that side is the only remedy.

Excision or Stretching of the Lingual Nerve.—Division of the lingual nerve was first put in practice by Hilton[41]; then Moore[42] advised a more simple procedure than Hilton's. This was to make an incision with a curved bistoury through the mucous membrane in a line from the last molar tooth to the angle of the jaw. The simplest method is as follows, and this method is suitable for division, excision, or stretching. The writer has practised it and found no difficulty in reaching the nerve. The mouth should be opened with a suitable gag, then a ligature is to be passed through the tongue near the tip, and the tongue drawn out to the side opposite to that on which it is desired to stretch the nerve; this puts the nerve on the stretch and it can be felt standing out as a cord at the side of the tongue: a sharp hook is passed under it, and then the nerve is exposed by a small incision, pulled out by a blunt hook, and excised or stretched as the necessities of the case may indicate. Mr. Clement Lucas[43] was the first, as far as the writer's knowledge goes, to put this plan in practice.

Francis J. Shepherd.

TONICS.—Tonics are medicines that promote nutrition and thus increase the strength of the body when it is reduced. The term tonic is derived from the Greek word *tonos*, tension, and was applied to agents that restore the normal strength, because it was supposed that they specially increase the tone or tension of the contractile tissues, that is, restore the constant, active, but weak, involuntary contraction normally existing in all organs containing such tissues. They were held to act either directly upon the contractile tissues, or upon the nerves by which they are innervated. This view is no longer entertained, as it is evident that the tone or strength of all organs and tissues depends upon the state of their nutrition, any diminution of which becoming manifest in more or less weakness and loss of functional power.

For practical purposes all tonic medicines may be divided into three classes: *gastric tonics*, *blood tonics* or *hæmatinics*, and *general tonics*. Gastric tonics improve the digestive process when it is enfeebled, thus enriching the blood, and supplying all the organs and tissues with an abundance of nutritive material. Blood tonics, or hæmatinics, supply the blood with material in which it is deficient, especially increasing the number of red blood corpuscles. General tonics increase the nutrition and weight of the body by augmenting or otherwise modifying the process of assimilation in the tissues.

GASTRIC TONICS.—Some of the medicines that improve the process of digestion when it is weak or imperfect, act directly upon the organs of digestion, enabling them to perform their function more powerfully; others, however, have no direct influence upon the stomach and intestines, and act only upon the substances undergoing digestion, hastening this process. The latter are distinguished from the former by the term *digestives*.

Nearly all gastric tonics have an intensely bitter taste, and act similarly upon the digestive organs. Hence they are called *bitter tonics*. Since they closely resemble one another in action, it is unnecessary to consider them separately, with the exception of the principal alkaloids of cinchona and nux vomica, which are supposed to promote nutrition by acting also upon other organs.

BITTER TONICS.—All bitter tonics increase the secretion of saliva, and, soon after coming into contact with the gastric mucous membrane, produce a feeling of hunger. In consequence of the stronger appetite a larger quantity of food is eaten. In cases of atonic dyspepsia the digestion of the large meal is not attended by the feeling of heaviness and discomfort, and other symptoms which usually result from slow and imperfect digestion, showing that the bitter tonics cause some decided improvement in the digestive process. This improvement, however, follows only when the bitter tonics are given in moderate doses; excessive doses, especially if frequently repeated, soon causing symptoms of gastro-intestinal catarrh, nausea, vomiting, and diarrhœa.

In regard to the mode of action of bitter tonics the following facts have been ascertained:

1. They increase the salivary secretion. The saliva hastens the digestion of amylaceous food and stimulates the gastric glands, and thus excites an abundant secretion of gastric juice. It has been held that this sufficiently accounts for their utility in cases of atonic dyspepsia (Leube).

2. They gently irritate the gastric mucous membrane, and thus, it is supposed, excite the feeling of hunger. As the larger quantity of food consumed is digested more easily and speedily in cases of dyspepsia, it may be assumed that the secretion of gastric juice becomes augmented, either directly by the moderate irritation, or indirectly by the greater relish of the food. It is supposed that in many cases of dyspepsia due to slight catarrh of the stomach, the moderate irritation gradually restores the normal circulation of the gastric mucous membrane.

3. In experiments it has been found that bitter tonics retard fermentation and putrefaction. The small doses usually effectual in atonic dyspepsia may doubtless exert some antiseptic influence, but it is improbable that their utility is chiefly due to this action.

4. Cetrarin and calumbin, injected into the jugular vein of animals, cause a rise of the general blood pressure by exciting the vaso-motor centre (Koehler). Hence it has been supposed that possibly all bitter tonics may to some extent act like digitalis, which, in indigestion dependent upon enfeebled heart action, improves the

digestive process by causing the supply of arterial blood to the stomach to be increased. But no changes of the blood pressure have been observed after the administration of bitter tonics until a notable improvement of the general nutrition of the body has resulted. It seems probable, however, that the action of quinine and strychnine upon the digestive organs is in part due to an improvement of the general circulation.

The bitter tonics display their therapeutic power most markedly in atonic dyspepsia, that is, in cases of dyspepsia in which the slow and imperfect digestion results solely from weakness of the stomach. In such cases the appetite is feeble, and the tongue clean or only thinly coated, and generally pale and flabby. Unless only very digestible food be eaten, in moderate quantities, the meals are soon followed by a feeling of weight in the epigastrium, and often by fulness and eructations which sometimes have a rancid taste. But decided pain in the region of the stomach, and thirst, fever, and vomiting are absent.

The bitter tonics are also employed in dyspepsia due to chronic catarrh of the stomach; generally small doses, in slight or mild cases, soon cause a notable abatement of the symptoms; but they generally aggravate severe catarrh, and are decidedly injurious in ulcerative affections of the stomach. They should therefore not be used when there are present severe pain and tenderness of the epigastrium, a heavily coated tongue, and vomiting of blood or large quantities of mucus.

As the bitter tonics improve general nutrition and strength solely by their action upon the digestive organs, they are useless in all forms of general or local debility which are not attended by enfeebled or disordered digestion.

As a rule, the bitter tonics should be given a short time before meals, so that a keen appetite may set in as soon as food is taken. Of the official preparations, the tinctures are the most useful in atonic dyspepsia; generally the compound tincture of gentian, the compound tincture of cinchona, the tincture of quassia, and the tincture of calumba are sufficiently active in doses of one-half to one drachm. The tincture of nux vomica is effective in doses of five to ten drops, and even smaller quantities sometimes in slight catarrh of the stomach.

If no other morbid state is present requiring active remedies, the bitter tinctures may be prescribed undiluted, the patient being told to take each dose in a small quantity of water or sweetened water. Sometimes they are ordered with a small quantity of syrup or with an aromatic water to modify their taste. The following formulæ illustrate the usual modes of prescribing in atonic dyspepsia: ℞ Tinct. cinchon. comp., ℥ iss.; syrupi, ℥ ss. M. Sig.: A teaspoonful in water before meals. ℞ Tinct. gentian. comp., ℥ iss.; syrup. aurantii, ℥ ss. M. Sig.: A teaspoonful in water before meals. ℞ Tinct. quassiæ, ℥ iss.; syrup. zingiberis, ℥ ss. M. Sig.: A teaspoonful before each meal. ℞ Tr. nucis vom., ʒ i.; aq. menth. pip., aq. destill., āā ℥ i. M. Sig.: A teaspoonful before each meal.

Quinine.—In dyspepsia due to weakness of the stomach the salts of quinine seem to act in the same manner as other bitter tonics. But they are more efficient than the latter when dyspepsia is associated with malarial affections, or is consequent upon pulmonary and cardiac diseases. Probably this is due to the fact that, given in moderate tonic doses, they somewhat increase the general blood pressure.

The opinion is prevalent that quinine may sustain the strength of the body under circumstances contraindicating bitter gastric tonics, such as prolonged fevers with a high temperature. Very commonly doses of two or three grains are given three or four times daily, or even more frequently, in typhoid fever, pneumonia, pleuritis, and other similar diseases. Whether this use of quinine is ever beneficial is very doubtful, and there is reason to suppose that in typhoid fever, especially if the quinine be not given in acid solution, it may increase the tendency to hemorrhage and perforation.

As gastric tonics the salts of quinine should be given in small doses, one-half to one grain, or at most two grains, preferably in solution. ℞ Quin. sulph., gr. xvi.; acid. hydrochl. dil., q.s.; tinct. cinchon. comp., syrup. aurantii, āā ℥ i. M. Sig.: A teaspoonful before each meal. ℞ Quininæ hydrochl., gr. xvi.; glycerini, ℥ ss.; aq. menth. pip., ℥ iss. M. Sig.: A teaspoonful before meals.

Strychnine.—The salts of strychnine are frequently employed as gastric tonics, and are very efficient. They are preferred to all other bitter medicines when feeble digestion is associated with diseases of the respiratory organs impairing the breathing process, such as phthisis, chronic bronchitis, and emphysema. Doses of one-thirtieth grain often notably ameliorate both dyspnœa and dyspepsia. In those diseases of the heart which are productive of disorder of the general circulation, and of slow and feeble digestion, strychnine also should be preferred to those bitter tonics which act solely on the digestive organs. In cases of dyspepsia complicated with habitual constipation, small doses of strychnine sometimes restore normal intestinal peristalsis. As a gastric tonic it should be given in solution or in powder. ℞ Strychn. sulph., gr. ss.; acid. hydrochl. dil., ʒ ss.; tinct. gentian. comp., syr. aurantii, āā ℥ i. M. Sig.: A teaspoonful before meals. ℞ Strychn. sulph., gr. ss.; sacch. lactis, ʒ i. M. Div. in partes æquales xvi. Sig.: One powder before each meal.

Alcohol.—As a tonic no substance is more beneficial when properly used, or more detrimental when abused, than alcohol. Taken in small quantities well diluted, as contained in some alcoholic beverages, especially light wines and malt liquors, it is doubtless the most pleasant and active remedy in cases of atonic dyspepsia. It was observed from time immemorial that wine, taken very moderately with meals, enables a weak stomach to digest food more easily and speedily, and increases the general vigor of the body. Hence the advice of St. Paul to Timothy: "Drink no longer water, but use a little wine for thy stomach's sake, and often infirmities."

In experiments it has been found that alcohol, applied in small quantity to the gastric mucous membrane, causes a more copious secretion of gastric juice than any other substance. Doubtless it is this action, a decided increase of the secretion of gastric juice when wine is taken with full meals, which augments the appetite and enables the stomach easily to dispose of the larger quantity of food. Taken in excessive quantity alcohol retards digestion and causes gastric catarrh. This effect always results if large quantities are rapidly imbibed so as to produce decided intoxication. It is frequently observed also in individuals who habitually drink to excess, especially in those who take ardent spirits before meals. Some persons, however, who indulge excessively in beer or light wine, do not exhibit any symptoms of gastric disorder.

In cases of atonic dyspepsia only light wine or malt liquor should be recommended for prolonged use, as the danger of excessive indulgence and hence injury to the stomach is much greater from ardent spirits. If it become necessary to use whiskey or other strong alcoholic, the patient should be warned against taking it undiluted before meals.

Alcohol is superior to other gastric tonics not only because it is more agreeable, but because it exerts a more favorable influence on general nutrition. It is now well established that alcohol is nearly completely consumed in the body, and that in undergoing oxidation it yields heat and other force, and thus behaves in the same manner as other non-nitrogenous food. Robust persons with strong digestive organs, who easily dispose of sufficient food to maintain perfect nutrition, do not require alcohol as a nutrient; but those who naturally have a weak stomach and "often infirmities," are decidedly benefited by moderate quantities.

Alcohol displays its greatest utility in diseases so profoundly disordering the digestive organs that little or no ordinary food can be digested. In typhoid fever it is often the means of saving life. As it requires no digestion and is quickly absorbed, it may be given when no gastric juice is secreted. In chronic wasting diseases in which the digestive process gradually becomes more and more enfeebled, alcohol is capable of maintaining for a long time a fair state of the general nutrition.

The quantity of alcohol to be taken for therapeutic purposes varies with the nature of the disease. In atonic dyspepsia a few ounces of wine with the principal meal often suffice. Many persons having a weak stomach prefer to take a small quantity of wine with a little bread or other light food between the ordinary meals. Thus they eat more frequently, but never overload the stomach.

In febrile diseases, when little or no ordinary food can be digested, alcohol should be administered, like other medicines, at regular intervals. The quantity to be given will depend chiefly upon the temperature and general condition of the patient. If the temperature is very high and ordinary food cannot be digested, more will be required than when the temperature is less elevated and the digestive power is somewhat better preserved. So, too, more is usually required when the patient is very weak than when he is in a fair state of strength. Whiskey or other form of spirits should always be diluted before administration.

In all cases in which patients seem to require the prolonged use of alcohol in any form, and its recommendation is deemed advisable, they should be informed that its excessive use will surely produce serious pathological changes, and that "1 gm. of absolute alcohol per kilogram (two pounds) of body weight is the average limit per diem that cannot safely be exceeded." (See article on *Alcohol*.)
